According to the Centers for Disease Control and Prevention (CDC), regional differences exist in smoking throughout the United States. The 11 states with the highest prevalence of current smoking are Kentucky, West Virginia, Louisiana, Ohio, Indiana, Missouri, Oklahoma, Arkansas, Mississippi, Tennessee, and Alabama. Those states with the lowest prevalence are Utah and California.

Education

Level of education attainment correlated with tobacco use. Of adults who had not completed high school, 23 percent smoked cigarettes (and of those with a GED, 37 percent smoked), whereas only 7 percent of college graduates smoked.

Psychiatric Patients

Psychiatrists must be particularly concerned and knowledgeable about tobacco use disorders because of the high proportion of psychiatric patients who smoke. Approximately 50 percent of all psychiatric outpatients, 70 percent of outpatients with bipolar I disorder, almost 90 percent of outpatients with schizophrenia, and 70 percent of patients with substance use disorder smoke. Moreover, data indicate that patients with depressive disorders or anxiety disorders are less successful in their attempts to quit smoking than other persons; thus, a holistic health approach for these patients probably includes helping them address their smoking habits in addition to the primary mental disorder. The high percentage of patients with schizophrenia who smoke may be due to tobacco's ability to reduce their extraordinary sensitivity to outside sensory stimuli and to increase their concentration. In that sense, such patients are self-monitoring to relieve distress.

Death

Death is the primary adverse effect of cigarette smoking. Tobacco use is associated with more than 400,000 premature deaths each year in the United States, which is 20 percent of all deaths. Individuals who smoke tend to die 10 years earlier than nonsmokers. Cancer causes chronic obstructive pulmonary disease, other lung diseases, cancer, heart disease, stroke, and diabetes. The increased use of chewing tobacco and snuff (smokeless tobacco) is associated with the development of oropharyngeal cancer.

Researchers have found that tobacco smoke causes nearly 30 percent of cancer deaths in the United States, making tobacco the single most lethal carcinogen in the United States. Smoking (mainly cigarette smoking) causes cancer of the lung, upper respiratory tract, esophagus, bladder, and pancreas and probably of the stomach, liver, and kidney. Smokers are 15 to 30 times more likely than nonsmokers to develop lung cancer, and lung cancer has

surpassed breast cancer as the leading cause of cancer-related deaths in women. Despite these staggering statistics, smokers can dramatically lower their chances of developing smoke-related cancers by merely quitting.

PATHOLOGY

Neuropharmacology

The psychoactive component of tobacco is nicotine, which affects the CNS by acting as an agonist at the nicotinic subtype of acetylcholine receptors. About 25 percent of the nicotine inhaled during smoking reaches the bloodstream, through which nicotine reaches the brain within 15 seconds. The half-life of nicotine is about 2 hours. Nicotine likely produces its positive reinforcing and addictive properties by activating the dopaminergic pathway projecting from the VTA to the cerebral cortex and the limbic system. In addition to activating this dopamine reward system, nicotine causes an increase in the concentrations of circulating norepinephrine and epinephrine and an increase in the release of vasopressin, β-endorphin, adrenocorticotropic hormone (ACTH), and cortisol. These hormones contribute to the primary stimulatory effects of nicotine on the CNS.

Adverse Effects of Nicotine

Nicotine is a highly toxic alkaloid. Doses of 60 mg in an adult are fatal secondary to respiratory paralysis; doses of 0.5 mg are delivered by smoking an average cigarette. In low doses, the signs and symptoms of nicotine toxicity include nausea, vomiting, salivation, pallor (caused by peripheral vasoconstriction), weakness, abdominal pain (caused by increased peristalsis), diarrhea, dizziness, headache, increased blood pressure, tachycardia, tremor, and cold sweats. Toxicity is also associated with an inability to concentrate, confusion, and sensory disturbances. Nicotine is further associated with a decrease in the user's amount of REM sleep. Tobacco use during pregnancy is associated with an increased incidence of low–birth-weight babies and an increased incidence of newborns with persistent pulmonary hypertension.

Health Benefits of Smoking Cessation

Smoking cessation has significant and immediate health benefits for persons of all ages and provides benefits for persons with and without smoking-related diseases. Former smokers live longer than those who continue to smoke. Smoking cessation decreases the risk of lung cancer and other cancers, myocardial infarction, cerebrovascular diseases, and chronic lung diseases. Women who stop smoking before pregnancy or during the first 3 to 4 months of pregnancy reduce their risk of having low–birth-weight infants to that of women who never smoked. The health benefits of smoking cessation substantially exceed any risks from the average 5-lb (2.3-kg) weight gain or any adverse psychological effects after quitting.

▲ 4.8 Caffeine-Related Disorders

Caffeine affects various neurobiologic and physiologic systems and produces significant psychological effects. Caffeine is not associated with any life-threatening illnesses, but its use can result in psychiatric symptoms and disorders. The habitual use of caffeine and its widely accepted integration into daily customs can lead to an underestimation of the role that caffeine may play in one's daily life and can make the recognition of caffeine-associated disorders particularly challenging. Hence, the clinician should be familiar with caffeine, its effects, and associated problems.

CLINICAL FEATURES AND DIAGNOSIS

Caffeine use is associated with five disorders: caffeine intoxication, caffeine withdrawal, caffeine use disorder, caffeine-induced anxiety disorder, and caffeine-induced sleep disorder. The diagnosis of caffeine intoxication or other caffeine-related disorders depends primarily on a comprehensive history of a patient's intake of caffeine-containing products. The history should cover whether a patient had experienced any symptoms of caffeine withdrawal during periods when caffeine consumption was either stopped or severely reduced. Table 4-33 lists some essential diagnoses to consider in the differential for caffeine-related disorders. The differential diagnosis should include the abuse of caffeine-containing OTC medications, anabolic steroids, and other stimulants, such as amphetamines and cocaine. A urine sample may

be needed to screen for these substances. The differential diagnosis should also include hyperthyroidism and pheochromocytoma.

Table 4-33
Differential Diagnosis for Caffeine-Related Disorders

Generalized anxiety disorder
Panic disorder with or without agoraphobia
Bipolar II disorder
Attention-deficit/hyperactivity disorder (ADHD)
Sleep disorders

Caffeine Intoxication

After the ingesting 50 to 100 mg of caffeine, the common symptoms can be pleasant (e.g., alertness) or only mildly annoying (diuresis). As the dose increases, the symptoms become more concerning; Table 4-34 lists these. Caffeine intoxication generally occurs above 250 mg. The annual incidence of intoxication is about 10 percent of the population. Above 10 g of caffeine—almost impossible to achieve with usual caffeinated beverages but possible with pills or other supplements—caffeine can be fatal.

Table 4-34
Symptoms and Signs of Caffeine Use

Mild to Moderate Use (50–100 mg)	Alertness	A mild sense of well-being	A sense of improved verbal and motor performance	Diuresis	Cardiac muscle stimulati

Table 4-35
Symptoms of Caffeine Withdrawal

Headache
Fatigue
Anxiety
Irritability
Mild depressive symptoms
Impaired psychomotor performance
Nausea
Vomiting
Craving for caffeine
Muscle pain and stiffness

Ms. B, a 30-year-old, went for consultation due to "anxiety attacks." The attacks occurred mid- to late afternoon when Ms. B became restless, nervous, and quickly excited and sometimes was noticed to be flushed, sweating, and, according to coworkers, "talking a mile a minute." In response to questioning, Ms. B admitted to consuming six to seven cups of coffee each day before the time the attacks usually occurred.

Caffeine Withdrawal

The appearance of withdrawal symptoms reflects the tolerance and physiologic dependence that develop with continued caffeine use. Several epidemiologic studies have reported symptoms of caffeine withdrawal in 50 to 75 percent of all caffeine users studied.

Table 4-35 lists the symptoms of caffeine withdrawal; the most common ones are headache and fatigue. The amount of caffeine and the abruptness of stopping it correlate with the number and severity of the withdrawal symptoms. Caffeine withdrawal symptoms begin about 12 to 24 hours after

the last dose, peak in 24 to 48 hours, and resolve within 1 week.

The induction of caffeine withdrawal can sometimes be iatrogenic. Physicians often ask their patients to discontinue caffeine intake before specific medical procedures, such as endoscopy, colonoscopy, and cardiac catheterization. Also, physicians often recommend that patients with anxiety symptoms, cardiac arrhythmias, esophagitis, hiatal hernias, fibrocystic disease of the breast, and insomnia stop caffeine intake. Some persons decide that it would be good for them to stop using caffeine-containing products. In all these situations, caffeine users should taper the use of caffeine-containing products over a 7- to 14-day period rather than stop abruptly.

Mr. F was a 43-year-old attorney whose wife brought him for a psychiatric consultation. Mr. F had been complaining of fatigue, loss of motivation, sleepiness, headache, nausea, and difficulty concentrating. His symptoms occurred mostly over the weekends. He withdrew from weekend social activities due to his symptoms, which worried Mrs. F because he seems fine during the week. Mr. F is in good health with no recent history of medical disorders.

Mr. F worked in hectic law practice, many times working 60-hour weeks, and barely sees his family during the week. At work, he is often anxious, restless, and always busy. He worries about his job so much that he has difficulty sleeping on weeknights. He denies any marital or family problems, apart from those related to his insisting on working on the weekend.

At work, Mr. F regularly consumes approximately four to five cups of coffee per day. He cut out coffee on the weekends because he felt that it might be contributing to his anxiety and sleeplessness.

Caffeine Use Disorder

Some people with problematic caffeine consumption might have a caffeine use disorder. DSM-5 includes this diagnosis in Section III, meant for conditions requiring further study. No studies have examined the course and prognosis for patients with a diagnosis of caffeine use disorder. Subjects with caffeine use disorder have reported continued use of caffeine despite repeated

efforts to discontinue their caffeine use.

Ms. G was a 35-year-old married homemaker with three children aged 8, 6, and 2. She took no prescription medications, took a multivitamin and vitamins C and E daily, did not smoke, and had no history of psychiatric problems. She drank moderate amounts of alcohol on the weekends, had smoked marijuana in college but had not used it since, and had no other history of illicit drug use.

She had started consuming caffeinated beverages while in college, and her current beverage of choice was caffeinated diet cola. Ms. G had her first soft drink early in the morning, shortly after getting out of bed, and she jokingly called it her "morning hit." She spaced out her bottles of soft drinks over the day, with her last bottle at dinnertime. She typically drank four to five 20-oz bottles of caffeinated diet cola each day.

She and her husband had argued about her caffeinated soft drink use in the past, and her husband had believed she should not drink caffeinated soft drinks while pregnant. However, she had continued to do so during each of her pregnancies. Despite a desire to stop drinking caffeinated soft drinks, she was unable to do so. She described having a strong desire to drink caffeinated soft drinks, and if she resisted this desire, she found that she could not think of anything else. She drank caffeinated soft drinks in her car, which had a manual transmission, and noted that she fumbled while shifting and holding the soft drink and spilled it in the car. She also noted that her teeth had become yellowed, and she suspected this was related to her tendency to swish the soft drink in her mouth before swallowing it. When asked to describe a time when she stopped using soft drinks, Ms. G reported that she ran out of it on the day one of her children was to have a birthday party, and she did not have time to leave her home to buy more. In the early afternoon of that day, a few hours before the scheduled start of the party, she felt extreme lethargy, a severe headache, irritability, and craving for a soft drink. She called her husband and told him she planned to cancel the party. She then went to the grocery store to buy soft drinks, and after drinking two bottles, she felt well enough to host the party.

Although initially expressing interest in decreasing or stopping her

caffeinated soft drink use, Ms. G did not attend scheduled follow-up appointments after her first evaluation. When finally contacted at home, she reported she had only sought help initially at her husband's request, and she had decided to try to cut down on her caffeine use on her own. (Courtesy of Eric Strain, M.D.)

Caffeine-Induced Disorders

Caffeine-Induced Anxiety Disorder. The anxiety related to caffeine use can resemble that of generalized anxiety disorder. Patients with the disorder may be perceived as "wired," overly talkative, and irritable; they may complain of not sleeping well and of having too much energy. Caffeine can induce and exacerbate panic attacks in persons with a panic disorder. Although there is no conclusive proof of a causative relation between caffeine and panic disorder, it is prudent to advise patients with panic disorder to avoid caffeine.

Mr. B was a 28-year-old male graduate student who was in good health and had no history of previous psychiatric evaluation or treatment. He took no medications, did not smoke or consume alcohol, and had no current or past history of illicit drug use.

His chief complaint was that he had begun feeling mounting "anxiety" when working in the laboratory where he was pursuing his graduate studies. His work had been progressing well, and he felt his relationship with his advisor was excellent and supportive, and he could not identify any problems with staff or peers that might explain his anxiety. He had been working long hours, but found the work exciting and had recently had his first paper accepted for publication.

Despite these successes, he reported feeling "crescendoing anxiety" as his day would progress. He noted that by the afternoon, he would be experiencing palpitations, bursts of his heart racing, tremors in his hands, and an overall feeling of "being on edge." He also noted nervous energy in the afternoons. These experiences were occurring daily and seemed confined to the laboratory (although he admitted he was in the laboratory

every day of the week).

During the history-taking, it became clear that Mr. B consumed large amounts of coffee. The staff made a large urn of caffeinated coffee each morning, and Mr. B routinely started with a large mug of coffee. Throughout the morning, he would consume three to four mugs of coffee (the equivalent of about six or eight 6-oz cups of coffee) and continued this for the afternoon. He occasionally had a single can of a caffeinated soft drink and used no other forms of caffeine regularly. Mr. B estimated that he drank a total of six to eight or more mugs of coffee per day (which was estimated to be at least 1,200 mg of caffeine per day). Once pointed out to him, he realized that this level of caffeine consumption was considerably higher than at any other time in his life. He admitted he liked the taste of coffee and felt a burst of energy in the morning when he drank coffee that helped him start his day.

Mr. B and his physician developed a plan to decrease his caffeine use by tapering off caffeine. Mr. B was successful in decreasing his caffeine use and had a reasonable resolution of his anxiety symptoms once his daily coffee use had markedly decreased. (Courtesy of Laura M. Juliano, Ph.D., and Roland R. Griffiths, Ph.D.)

Caffeine-Induced Sleep Disorder. Caffeine is associated with a delay in falling asleep, inability to remain asleep, and early morning awakening.

Caffeine-Related Disorder Not Elsewhere Classified. This category includes caffeine-related disorders that do not meet the criteria for caffeine use disorder, caffeine intoxication, caffeine withdrawal, caffeine-induced anxiety disorder, or caffeine-induced sleep disorder.

COMORBIDITY

Persons with caffeine-related disorders are more likely to have additional substance-related disorders than are those without diagnoses of caffeine-related disorders. About two-thirds of those who consume large amounts of caffeine daily also use sedative and hypnotic drugs. Significant caffeine consumption is associated with major depression, generalized anxiety disorder, panic disorder, antisocial personality disorder, and other substance

use disorders, including alcohol, cannabis, and cocaine.

Caffeine Use and Nonpsychiatric Illnesses

Despite a great deal of research, no one has conclusively demonstrated a significant health risk from routine caffeine use. Nonetheless, caffeine use is considered relatively contraindicated for various conditions; Table 4-36 lists these. Some of these are very controversial; for example, there may be a mild association between higher-daily caffeine use in women and delayed conception and slightly lower birth weight. Studies, however, have not found such associations, and effects, when found, are usually with relatively high daily dosages of caffeine (e.g., the equivalent of five cups of brewed coffee per day). For a woman who is considering pregnancy, especially if there is some difficulty in conceiving, it may be useful to counsel stopping caffeine use. Similarly, for a woman who becomes pregnant and has moderate- to high-daily caffeine consumption, a discussion about decreasing her daily caffeine use may be warranted.

Table 4-36
Possible Contraindications to Caffeine Use

Generalized anxiety disorder
Panic disorder
Primary insomnia
Gastroesophageal reflux
Cardiovascular disease (particularly hypertension and
  hypercholesterolemia)
Pregnancy
Infertility

TREATMENT

Analgesics, such as aspirin, usually control the headaches and muscle aches that may accompany caffeine withdrawal. Rarely do patients require benzodiazepines to relieve withdrawal symptoms. When using benzodiazepines, we should restrict them to small doses and short durations,

about 7 to 10 days at the longest.

The first step to reducing or eliminating caffeine is to have the patient determine their daily consumption of caffeine. A daily food diary can help determine an accurate dose. We may have to educate the patient about the many sources of caffeine in the diet. After several days of diet tracking, we can review the diary with the patient and determine the average-daily caffeine dose.

After obtaining an accurate accounting of all caffeine use, we can work with the patient to decide on a reasonable taper. A typical schedule would be a decrease of 10 percent every few days. Because most of the caffeine usually comes from beverages, gradually substituting decaffeinated beverages for caffeinated ones can be a simple strategy. The diary should be maintained, and the progress monitored. The tapering should be individualized for each patient so that the rate of caffeine decrease minimizes withdrawal symptoms. Although abrupt withdrawal is possible, most patients find the withdrawal too uncomfortable.

EPIDEMIOLOGY

Caffeine is the most widely consumed psychoactive substance in the world. In the United States, 87 percent of children and adults consume foods and beverages containing caffeine. Caffeine is found in more than 60 species of plants and belongs to the methylxanthine class of alkaloids, which also includes theobromine (found in chocolate) and theophylline (often used in the treatment of asthma).

Many drinks, foods, prescription medicines, and OTC medicines contain caffeine (Table 4-37). The mean caffeine intake among adults (over age 22) in the United States was estimated to be 300 mg/day, although, among coffee drinkers, the mean intake was 375 mg/day. A cup of coffee generally contains 100 to 150 mg of caffeine; tea contains about one-third as much. Many OTC medications contain one-third to one-half as much caffeine as a cup of coffee, and some migraine medications and OTC stimulants contain more caffeine than a cup of coffee. Cocoa, chocolate, and soft drinks contain significant amounts of caffeine, enough to cause some symptoms of caffeine intoxication in small children when they ingest a candy bar and a 12-oz cola drink.

Table 4-37
Caffeine Content of Common Foods and Medications

Product	Serving Size (Volume or Weight)	Typical Caffeine Content (mg)	Range (mg)
BEVERAGES			
Coffee

Caffeine content of decaffeinated coffee. *J Anal Toxicol*. 2006;30(8):611; McCusker RR, Goldberger BA, Cone EJ. Caffeine content of specialty coffees. *J Anal Toxicol*. 2003;27(7):520.

Special Populations

Cigarette smokers consume more caffeine than nonsmokers. This observation may reflect a shared genetic vulnerability to caffeine use and cigarette smoking. It may also be related to increased rates of caffeine elimination in cigarette smokers. Preclinical and clinical studies indicate that regular caffeine use can potentiate the reinforcing effects of nicotine.

Heavy use and clinical dependence on alcohol are associated with heavy use and clinical dependence on caffeine as well. Individuals with anxiety disorders tend to report lower levels of caffeine use, although one study showed that a more significant proportion of heavy caffeine consumers also use benzodiazepines. Several studies have also shown high-daily amounts of caffeine use in psychiatric inpatients. For example, several studies have found that such patients consume the equivalent of an average of five or more cups of brewed coffee each day. Finally, high-daily caffeine consumption occurs in prisoners.

PATHOLOGY AND ETIOLOGY

After exposure to caffeine, several factors influence continued consumption, such as the pharmacologic effects of caffeine, caffeine's reinforcing effects, genetic predispositions to caffeine use, and personal attributes of the consumer.

Neuropharmacology. Caffeine, a methylxanthine, is more potent than the other methylxanthine, theophylline. The half-life of caffeine in the human body is 3 to 10 hours, and the time of peak concentration is 30 to 60 minutes. Caffeine readily crosses the blood–brain barrier. Caffeine acts primarily as an antagonist of adenosine receptors. Adenosine receptors activate an inhibitory G protein (G_i), which then inhibits the formation of the second-messenger cyclic adenosine monophosphate (cAMP). Caffeine intake, therefore, results in an increase in intraneuronal cAMP concentrations in neurons with adenosine receptors.

Three cups of coffee are estimated to deliver enough caffeine to the brain caffeine to occupy about 50 percent of the adenosine receptors. Several experiments indicate that caffeine, especially at high doses or concentrations, can affect dopamine and noradrenergic neurons. Specifically, caffeine may enhance dopamine activity, a hypothesis that could explain clinical reports associating caffeine intake with an exacerbation of psychotic symptoms in patients with schizophrenia. Activation of noradrenergic neurons may be involved in the mediation of some symptoms of caffeine withdrawal.

Subjective Effects and Reinforcement. The subjective effect of single low to moderate doses of caffeine (i.e., 20 to 200 mg) is usually pleasurable. Studies have shown that these doses result in increased ratings on measures such as well-being, energy and concentration, and motivation to work. Also, these doses of caffeine produce decreases in ratings of feeling sleepy or tired. In the range of 300 to 800 mg (the equivalent of several cups of brewed coffee ingested at once), subjects tend to rate the effects of caffeine as more unpleasant, with feelings of anxiety and nervousness. Animal studies have generally found it difficult to demonstrate that caffeine functions as a reinforcer. However, well-controlled studies in humans have shown that people choose caffeine over placebo when given a choice under controlled experimental conditions. In habitual users, caffeine's ability to suppress withdrawal symptoms also reinforces the effects of caffeine. Thus, the profile

of caffeine's subjective effects and its ability to function as a reinforcer contribute to the regular use of caffeine.

Genetics and Caffeine Use. Some genetic predisposition may exist to continued coffee use after exposure to coffee. Some studies have shown higher concordance rates for monozygotic twins for total caffeine consumption, heavy use, caffeine tolerance, caffeine withdrawal, and caffeine intoxication, with heritabilities ranging between 35 and 77 percent. Multivariate structural equation modeling of caffeine use, cigarette smoking, and alcohol use suggest that a common genetic factor—polysubstance use—underlies the use of these three substances.

Effects on Cerebral Blood Flow. Most studies have found that caffeine results in global cerebral vasoconstriction, with a resultant decrease in CBF, although this effect may not occur in persons over 65 years of age. According to one study, tolerance does not develop to these vasoconstrictive effects, and the CBF shows a rebound increase after withdrawal from caffeine. Some clinicians believe that caffeine use can cause a similar constriction in the coronary arteries and produce angina in the absence of atherosclerosis.

▲ 4.9 Hallucinogen-Related Disorders

CLINICAL FEATURES

Hallucinogens, by definition, are intoxicants. Table 4-38 lists some of the psychological effects of hallucinogenic drugs. Hallucinations are usually visual, often of geometric forms and figures, but auditory and tactile hallucinations can occur. The sense of self is much changed, sometimes to the point of depersonalization, merging with the external world to the point of feeling separation of oneself from one's body.

**Table 4-38
Psychological Effects of Hallucinogens**

Heightened perceptions (richer colors, sharpened contours, richer

responses to music, smells or tastes)
Synesthesia
Changes in body image
Alterations in time and space
Intense, labile emotions
Suggestibility
Either sensitivity or detachment from others
Awareness of internal organs
The recovery of lost early memories
The release of unconscious material in symbolic form
Regression and the apparent reliving of past events, including birth
Introspective reflection and feelings of religious and philosophical
   insight
Depersonalization
Derealization
Anxiety, panic attacks
Flashbacks (hallucinogen-persisting perception disorder)
Mood disorders
Anxiety disorders
Psychosis
Delirium

Table 4-39
Overview of Representative Hallucinogens

Agent	Locale	Chemical Classification	Biologic Sources	Common Route	Typical Dose	Duration of Effects	Adverse Reactions
Lysergic acid diethylamide (LSD)	Globally distributed, semisynthetic	Indolealkylamine	Fungus in rye yields lysergic acid	Oral	100 μg	6–12 hr	Extensive, including pandemic 1965–1975
Mescaline	Southwestern US	Phenethylamine	Peyote cactus, *l. Williamsii*	Oral	200–400 mg or 4–6 cactus buttons	10–12 hr	Little or none verified
Methylenedioxyamphetamine (MDA)	US, synthetic	Phenethylamine	Synthetic	Oral	80–160 mg	8–12 hr	Documented
Methylenedioxymethamphetamine (MDMA)	US, synthetic	Phenethylamine	Synthetic	Oral	80–150 mg	4–6 hr	Documented
Psilocybin	Southern US, Mexico, south America	Phosphorylated hydroxylated DMT	Psilocybin mushrooms	Oral	4–6 mg or 5–10 g of dried mushroom	4–6 hr	Psychosis
Ibogaine	West central Africa	Indolealkylamine	Tabernanthe iboga	Eating powdered root	200–400 mg	8–48 hr	CNS excitation, death?
Ayahuasca	South American tropics	Harmine, other β-carbolines	Bark or leaves of *Banisteriopsis Caapi*	As a tea	300–400 mg	4–8 hr	None reported
Dimethyltryptamine	South America, synthetic	Substituted tryptamine	leaves of *Virola Calophylla*	As a snuff, iv	0.2 mg/kg iv	30 min	None reported
Morning glory	American tropics and warm zones	D-lysergic acid alkaloids	Seeds of *Ipomoea Violacea, Turbina Corymbosa*	Orally as infusion	7–13 seeds	3 hr	Toxic delirium
Nutmeg and mace	Warm zones of Europe, Africa, Asia	Myristicin and aromatic ethers	Fruit of *m. Fragrans*, commercial species	Orally or as a snuff	1 teaspoon, 5–15 g	Unknown	Similar to atropinism, with seizures, death
Yopo/Cohoba	Northern South America, Argentina	β-carbolines and tryptamines	Beans of *Anademanthera Peregrina*	Smoked or as a snuff	Unknown	Unknown	Ataxia, hallucinations, seizures?
Bufotenin	Northern south America, Argentina	5-OH-dimethyl-tryptamine	Skin glands of toads; seeds of *A. Peregrina*	As a snuff or IV	Unknown	15 min	None reported
Phencyclidine (PCP)	US, synthetic	1-phenylcyclohexylpiperidine	Synthetic	Oral, smoked, as a snuff, IV	5–10 mg	4–6 hr	Psychotic
Ketamine	US, synthetic	(+/-)-2-(2-chlorophenyl)-2-(methylamino)-cyclohexanone	Synthetic	Oral, snorted, IV		1–2 hr	Psychotic

Adapted from Henry David Abraham, MD.

Specific Substances

Hallucinogens are natural and synthetic substances that are variously called *psychedelics* or *psychotomimetics.* The hallucinogens are classified as Schedule I controlled substances; the US FDA has decreed that they have no medical use and high abuse potential.

Table 4-39 lists some natural and synthetic hallucinogens. The most common naturally occurring hallucinogens are psilocybin, derived from certain mushrooms, and mescaline, derived from peyote cactus. The classic synthetic hallucinogen is LSD, synthesized in 1938 by Albert Hoffman, who accidentally ingested the drug and experienced the first LSD trip. Some researchers include some of the so-called designer amphetamines, such as 3,4-methylenedioxyamphetamine (MDMA), as hallucinogens, but we include them among the stimulants.

Phencyclidine and Ketamine. Phencyclidine (PCP; 1-1 [phenylcyclohexyl] piperidine), also known as *angel dust,* was developed as a novel anesthetic in the late 1950s. This drug and the closely related compound ketamine were called *dissociative anesthetics,* because subjects

taking them were awake but insensitive to, or dissociated from, the environment. Phencyclidine and ketamine exert their unique behavioral effects by blocking NMDA-type receptors for the excitatory neurotransmitter glutamate. They can cause a variety of symptoms, from anxiety to psychosis. Phencyclidine and ketamine are classified as Schedule II and Schedule III controlled substances, respectively. Although somewhat different from standard hallucinogens, both DSM-5 and we include among the hallucinogens given their psychological effects.

LSD. LSD is the prototype for a large class of hallucinogenic compounds with well-studied structure–activity relationships. LSD is a synthetic base derived from the lysergic acid nucleus from the ergot alkaloids. That family of compounds was discovered in rye fungus and was responsible for lethal outbreaks of St. Anthony's fire in the Middle Ages. The compounds are also present in morning glory seeds in low concentrations. Researchers have studied many homologs and analogs of LSD, but none more potent than LSD.

Table 4-40 lists the physiologic symptoms from LSD, which are typically few and mild. Usually, somatic symptoms appear first, then mood and perceptual changes, and, finally, psychological changes. The effects may overlap, and depending on the particular hallucinogen, the time of onset and offset varies. The intensity of LSD effects in a nontolerant user generally is proportional to dose, with 25 µg as an approximate threshold dose.

The significant difference between LSD, psilocybin, and mescaline is potency. A 100-µg dose of LSD is roughly equivalent to 10 to 15 mg of psilocybin, which is equivalent to 300 to 400 mg of mescaline. With mescaline, the onset of symptoms is slower and more nausea and vomiting occur, but in general, the perceptual effects are more similar than different.

Tolerance, particularly to the sensory and other psychological effects, is evident as soon as the second or third day of repeated LSD use. Four to 6 days free of LSD is necessary to lose significant tolerance. Tolerance is associated with frequent use of any of the hallucinogens.

Table 4-40
Physiologic Symptoms of LSD

Common:

Dilated pupils
Increased deep tendon motor reflexes
Muscle tension
Mild motor incoordination
Ataxia

Occasional:
Increased heart rate
Increased respiration
Hypertension
Nausea
Decreased appetite
Salivation
Sweating
Blurred vision

Cross-tolerance among these hallucinogens occurs, but not between amphetamine and LSD, despite the chemical similarity of amphetamine and mescaline. Previously distributed as tablets, liquid, powder, and gelatin squares, in recent years, LSD has been commonly distributed as "blotter acid." Sheets of paper are soaked with LSD, and dried and perforated into small squares. Manufacturers stamp popular designs on the paper. Each sheet contains as many as a few hundred squares; one square containing 30 to 75 µg of LSD is one chewed dose, more or less. Planned massive ingestion is uncommon but massive ingestion happens by accident.

The onset of action of LSD occurs within an hour, peaks in 2 to 4 hours, and lasts 8 to 12 hours. LSD is a sympathomimetic, and death caused by cardiac or cerebrovascular pathology related to hypertension or hyperthermia can occur. Some reports suggest that LSD can cause a syndrome similar to neuroleptic malignant syndrome. Death can also result from physical injury when LSD impairs a person's judgment: people may run into traffic or attempt to fly. The psychological effects are usually well tolerated, but when persons cannot recall experiences or appreciate that the experiences are substance-induced, they may fear the onset of insanity.

There is no clear evidence that LSD causes drastic personality changes or

chronic psychosis. Some heavy users of hallucinogens, however, may experience chronic anxiety or depression.

Many persons maintain that a single experience with LSD has given them an increased creative capacity, new psychological insights, relief from neurotic or psychosomatic symptoms, or a desirable change in personality. In the 1950s and 1960s, researchers were interested in the possible pharmacologic effects of LSD. However, results have been inconsistent. The principal value of these drugs for science has been for the basic neurosciences.

Phenethylamines. Phenethylamines are compounds with chemical structures similar to those of the neurotransmitters dopamine and norepinephrine. Mescaline (3,4,5-trimethoxyphenethylamine), a classic hallucinogen in every sense of the term, was the first hallucinogen and is described below.

Another series of phenethylamine analogs with hallucinogenic properties is the 3,4-methylenedioxyamphetamine (MDA)–related amphetamines. MDMA or ecstasy is the currently most popular and, to society, the most troublesome member of this large family of drugs. It is more a relatively mild stimulant than a hallucinogen. MDMA produces an altered state of consciousness with sensory changes and, most notable for some users, a feeling of enhanced personal interactions.

MESCALINE. Mescaline derives from the peyote cactus, which grows in the southwestern United States and northern Mexico. Mescaline human pharmacology was characterized in 1896 and synthesized 23 years later. Although we have recognized many psychoactive plants since antiquity, only mescaline's structure was understood, until we discovered LSD.

People usually take mescaline as peyote "buttons," picked from the small blue-green cacti *Lophophora williamsii* and *Lophophora diffusa.* The buttons are the dried, round, fleshy cacti tops. Mescaline is the active hallucinogenic alkaloid in the buttons. The use of peyote is legal for the Native American Church members in some states. Adverse reactions to peyote are rare during structured religious use. Peyote usually is not consumed casually because of its bitter taste and sometimes severe nausea and vomiting that precede the hallucinogenic effects.

The many structural variations of mescaline are relatively well characterized. One analog, 2,5-dimethoxy-4-methylamphetamine (DOM), also known as STP, an unusually potent amphetamine with hallucinogen properties, had a relatively brief period of illicit popularity in the 1960s. However, it appears to have disappeared from the illicit market.

Psilocybin and Its Analogs. An unusual collection of tryptamines has its origin in the world of fungi. The natural prototype is psilocybin itself. As many as 100 species of mushroom, mainly of the *Psilocybe* genus contain psilocybin or related homologs.

People usually ingest psilocybin as mushrooms. Many species of psilocybin-containing mushrooms exist worldwide. In the United States, large *Psilocybe cubensis* (gold caps) grow in Florida and Texas and are easily grown with cultivation kits advertised in drug-oriented magazines and on the internet. The tiny *Psilocybe semilanceata* (liberty cap) grows in lawns and pastures in the Pacific Northwest. Psilocybin remains active when the mushrooms are dried or cooked into foods.

Psilocybin mushrooms are used in religious activities by Mexican Indians. They are valued in Western society by users who prefer to ingest a mushroom rather than a synthetic chemical. Of course, one danger of eating wild mushrooms is misidentification and ingestion of a poisonous variety.

Although not originating from mushrooms, another analog of psilocybin is N,N-dimethyltryptamine (DMT). Many plants contain this substance, which is also found normally in human biofluids at very low concentrations. When DMT is taken parenterally or by sniffing, a brief, intense hallucinogenic episode can result. As with mescaline, DMT is one of the oldest, best documented, but least potent of the tryptamine hallucinogens. Researchers have evaluated synthesized homologs of DMT in humans, and have described the structure–activity relationships.

Phencyclidine. Phencyclidine and its related compounds are sold as a crystalline powder, paste, liquid, or drug-soaked paper (blotter). Most commonly, drug dealers add PCP to a cannabis- or parsley-containing cigarette. Experienced users report that the effects of 2 to 3 mg of smoked PCP occur in about 5 minutes and plateau in 30 minutes. The bioavailability of PCP is about 75 percent when taken by intravenous administration and

about 30 percent when smoked. The half-life of PCP in humans is about 20 hours, and the half-life of ketamine in humans is about 2 hours.

Table 4-41
Effects of PCP

Physical
Nystagmus
Hypertension
Hyperthermia
Less common:
    Head-rolling movements
    Stroking
    Grimacing
    Muscle rigidity on stimulation
    Vomiting

Psychological
Euphoria
Labile emotions
Bodily warmth
Tingling
Peaceful floating sensations
Depersonalization
Feelings of isolation and estrangement
Auditory and visual hallucinations
Alterations of body image
Distortions of space and time perception
Paranoia
Delusions
Intensified dependence
Confusion
Disorganization of thought
Irritability

Depression
Behavioral
Repetitive chanting speech
Aggressive behavior

The amount of PCP varies greatly from PCP-laced cigarette to cigarette; 1 g can make as few as four or as many as several dozen cigarettes. Less than 5 mg of PCP is considered a low dose, and doses above 10 mg are considered high. Dose variability makes it difficult to predict the effect, although smoking PCP is the easiest and most reliable way for users to titrate the dose.

Persons who have just taken PCP are frequently uncommunicative, appear to be oblivious, and report active fantasy production. They can have a range of side effects, such as those listed in Table 4-41.

The short-term effects last 3 to 6 hours and sometimes give way to a mild depression in which the user becomes irritable, somewhat paranoid, and occasionally belligerent or assaultive. The effects can last for several days. Users sometimes find that it takes 1 to 2 days to recover completely; laboratory tests show that PCP can remain in the patient's blood and urine for more than a week.

Ketamine. Ketamine is a dissociative anesthetic agent, derived initially from PCP, which is available for use in human and veterinary medicine. It has become a drug of abuse, with sources primarily from stolen supplies. It is available as a powder or in a solution for intranasal, oral, inhalational, or (rarely) intravenous use. Ketamine functions by working at the NMDA receptor and, as with PCP, can cause hallucinations and a dissociated state in which the patient has an altered sense of the body and reality and little concern for the environment.

Ketamine causes cardiovascular stimulation and no respiratory depression. On physical examination, the patient may be hypertensive and tachycardic, have increased salivation and bidirectional or rotary nystagmus, or both. The onset of action is within seconds when used intravenously, and analgesia lasting 40 minutes and dissociative effects lasting for hours may occur. Clinicians should monitor a patient's cardiovascular status and administer supportive care. There have been reports of dystonic reactions and

flashbacks, but a more common complication is a lack of concern for the environment or personal safety.

Ketamine has a briefer duration of effect than PCP. Peak ketamine levels occur approximately 20 minutes after intramuscular injection. After intranasal administration, the duration of effect is approximately 1 hour. Ketamine is N-demethylated by liver microsomal cytochrome P450 (CYP), especially CYP3A, into norketamine. Ketamine, norketamine, and dehydronorketamine are detectable in urine, with half-lives of 3, 4, and 7 hours, respectively. Urinary ketamine and norketamine levels vary widely from individual to individual and can range from 10 to 7,000 ng/mL after intoxication. As of yet, there are no formal studies of the relationship between serum ketamine levels and clinical symptoms. Often, Ketamine is combined with other drugs of abuse, especially cocaine. Ketamine may enhance cocaine metabolism. Recent years have seen a growing number of ketamine infusion clinics for the treatment of depression, along with the FDA approval of esketamine nasal spray for treatment-resistant depression.

Additional Hallucinogens

CANTHINONES. Canthinones are alkaloids similar to amphetamines naturally found in the khat plant and synthetically made and known as "bath salts." They are CNS stimulants that cause a massive release of dopamine, and a single dose can last up to 8 hours. They produce profound toxic effects that can lead to seizures, strokes, or death. Hallucinations and delusions are common. They are swallowed, injected, or "snorted" to produce the desired euphoric effect.

IBOGAINE. Ibogaine is a complex alkaloid found in the African shrub *Tabernanthe iboga.* Ibogaine is a hallucinogen at the 400-mg dose range. The plant originates in Africa, where it is used in traditional ceremonies. It has not been a popular hallucinogen because of its unpleasant somatic effects when taken at hallucinogenic doses. However, psychiatrists may encounter patients exposed to ibogaine because of therapeutic claims.

AYAHUASCA. Ayahuasca, currently a popular subject of internet hallucinogen websites, initially referred to a decoction from one or more South American

plants. The substance contains the alkaloids harmaline and harmine. Both of those β-carboline alkaloids have hallucinogenic properties, but it also causes significant nausea. Amazon tribes discovered that adding leaves from plants containing substantial amounts of DMT enhanced the visual and sacramental impact of ayahuasca. Thus, when people use ayahuasca, it is often in combination with other drugs.

In recent years, the term *ayahuasca* has evolved to a less specific term to refer to any mixture of two things that are hallucinogenic when taken in combination. For example, harmine and harmaline are available as fine chemicals and, when taken along with many botanicals containing DMT, result in a mixture with hallucinogen properties, initially intense but usually of brief duration.

SALVIA DIVINORUM. American Indians in northern Oaxaca, Mexico, have used *Salvia divinorum* as a medicine and as a sacred sacrament, which is now widely discussed, advertised, and sold on the internet. Chewing the plant or smoking dried leaves can produce hallucinogen effects. Salvinorin-A, an active component in the plant, is parenterally potent, active at 250-µg doses when smoked, and of scientific and potential medical interest because it binds to the opioid κ-receptor.

DIAGNOSIS

Hallucinogen Use Disorder

Long-term hallucinogen use is uncommon. Some long-term users of PCP are said to be "crystallized," a syndrome characterized by dulled thinking, decreased reflexes, loss of memory, loss of impulse control, depression, lethargy, and impaired concentration. Although psychological dependence occurs, it is rare, in part because each LSD experience is different and in part because there is no reliable euphoria.

B, a 16-year-old boy from divorced parents, was admitted to the psychiatric unit of a local hospital. During the previous night, he slashed his wrists, severing nerves and tendons in his left hand, and drifted in and out of consciousness during the night. He finally contacted the mother of

a friend who lived nearby in the morning who immediately brought him to the hospital.

B had a history of juvenile delinquency from the age of 13 when he began hanging out with some older boys at his junior high school. He and his friends shoplifted, stole, smoked marijuana, and took LSD. B's grades dropped, and he got in trouble at school on two occasions for getting into fights with other students.

On admission, B stated that he did not intend to commit suicide when he slashed his wrist. After some questioning, he revealed that he had been "dropping acid" with some friends, and after they left, he thought he heard the sirens of police cars approaching his home. He did not wish to get arrested, so he slashed his wrist and then lost consciousness. He denies feeling depressed, although he claims his life is pointless and felt it made no difference whether he lived or died.

Hallucinogen Intoxication

The hallmarks of hallucinogen intoxication are maladaptive behavioral and perceptual changes, along with particular physiologic signs (Table 4-42). The differential diagnosis for hallucinogen intoxication includes anticholinergic and amphetamine intoxication and alcohol withdrawal. The preferred treatment for hallucinogen intoxication is talking down the patient; during this process, guides can reassure patients that the symptoms are drug-induced, that they are not going crazy, and that the symptoms will resolve shortly. In the most severe cases, dopaminergic antagonists—for example, haloperidol—or benzodiazepines—for example, diazepam—can be used for a limited time. Hallucinogen intoxication usually lacks a withdrawal syndrome.

Table 4-42
Physiologic Changes from Hallucinogens

1. Pupillary dilation
2. Tachycardia
3. Sweating
4. Palpitations

5. Blurring of vision
6. Tremors
7. Incoordination

Short-term PCP intoxication can have potentially severe complications and should be considered a psychiatric emergency. Some patients may present within hours of ingesting PCP, but often 2 to 3 days elapse before they seek psychiatric help. Persons who lose consciousness are brought for help earlier than those who remain conscious. Most patients recover completely within a day or two, but some remain psychotic for as long as 2 weeks. Patients presenting in a coma often exhibit disorientation, hallucinations, confusion, and difficulty communicating on regaining consciousness. These symptoms may also occur in noncomatose patients, but their symptoms appear to be less severe. Behavioral disturbances sometimes are severe; they can include public masturbation, stripping off clothes, violence, urinary incontinence, crying, and inappropriate laughing. Patients frequently have amnesia for the entire period of the psychosis.

Police brought a 17-year-old male patient to the emergency room after finding him disoriented on the street. As the police attempted to question him, he became increasingly agitated; when they attempted to restrain him, he became assaultive. Attempts to question or to examine him in the emergency department evoked increased agitation.

Initially, it was impossible to determine vital signs or to draw blood. Based on the observation of horizontal, vertical, and rotatory nystagmus, clinicians made a preliminary diagnosis of PCP intoxication. Within a few minutes of being placed in a darkened examination room, his agitation markedly decreased. Blood pressure was 170/100; other vital signs were within normal limits. The patient agreed to take 20 mg of diazepam orally. Thirty minutes later, he was less agitated and could be interviewed, although he responded to questions in a fragmented fashion and was slightly dysarthric. He stated that he must have inadvertently taken a larger-than-usual dose of "dust," which he reported having used once or twice a week for several years. He denied using any other substance and any history of mental disorder. He was confused and

disoriented to time and place. The qualitative toxicology screen revealed PCP and no other drugs. Results of neurologic examination were within normal limits, but he had brisk deep tendon reflexes. Some 90 minutes after arrival, his temperature, initially normal, was elevated to 38°C, his blood pressure had increased to 182/110, and he was poorly responsive to stimulation. He was admitted to a medical bed. His blood pressure and level of consciousness continued to fluctuate over the ensuing 18 hours. Results of hematologic and biochemical analyses of blood, as well as urinalyses, remained within normal limits. A history obtained from his family revealed that the patient had had multiple emergency room visits for complications from PCP use during the previous several years. He had completed a 30-day residential treatment program and had participated in several outpatient programs but had consistently relapsed. The doctors discharged the patient, with a referral to an outpatient treatment program, after his vital signs and level of consciousness had been within normal limits for 8 hours. At discharge, nystagmus and dysarthria were no longer present. (Courtesy of Daniel C. Javitt, M.D., Ph.D., and Stephen R. Zukin, M.D.)

Hallucinogen-Persisting Perception Disorder

Long after ingesting a hallucinogen, a person can experience a flashback of hallucinogenic symptoms. The DSM-5 calls this syndrome *hallucinogen-persisting perception disorder* and ICD-10 refers it as post hallucinogen perception disorder. Table 4-43 lists the comparative criteria for each disorder.

According to studies, from 15 to 80 percent of users of hallucinogens report having experienced flashbacks. They can be triggered by emotional stress, sensory deprivation (e.g., monotonous driving), or use a psychoactive substance, such as alcohol or marijuana.

Flashbacks are spontaneous, transitory recurrences of the substance-induced experience. Table 4-44 gives some examples of flashbacks. The episodes usually last a few seconds to a few minutes, but sometimes last longer. Most often, even in the presence of distinct perceptual disturbances, the person has insight into the pathologic nature of the disturbance. Suicidal behavior, major depressive disorder, and panic disorder are potential

complications.

When diagnosing this disorder several other similar syndromes should be considered in the differential. Migraines and seizures can cause flashback-like experiences. Posttraumatic stress disorder (PTSD) can also cause flashbacks. In addition, a variety of visual system abnormalities can cause perceptual problems that may resemble flashbacks.

Table 4-43
Flashbacks

	Flashbacks Due to Hallucinogen Use	
Disorder	**DSM-5**	**ICD-10**
Diagnostic name	Hallucinogen-Persisting Perception Disorder	Post hallucinogen perception disorder
Symptoms	1. Reexperiencing, following cessation of use, of perceptual symptoms that were present during intoxication 2. Symptoms cause distress or functional impairment	• Substance-induced changed in cognition, personality, affect, behavior persisting beyond generally accepted period, with onset of symptoms directly related to use of substance • Flashbacks are episodic, short duration, and frequently identical or similar to perceptual distortions experienced during acute intoxication
Required number of symptoms	Both of the above	

Psychosocial consequences of symptoms	Significant distress and/or impairment	
Exclusions	**Result of:** • Medical condition • Another mental disorder	**Result of:** • Alcohol- or psychoactive substance-induced Korsakov syndrome • Alcohol- or psychoactive substance-induced psychotic state

 Table 4-44
Examples of Flashbacks

Visual distortion

Geometric hallucinations

Hallucinations of sounds or voices

False perceptions of movement in peripheral fields

Flashes of color

Trails of images from moving objects

Positive afterimages and halos

Macropsia

Micropsia

Time expansion

Physical symptoms

Relived intense emotions

A 20-year-old undergraduate presented with a chief complaint of "seeing the air." The visual disturbance consisted of perception of white pinpoint specks too numerous to count in both the central and peripheral visual fields. They were always present along with the perception of trails of moving objects left behind as they passed through the patient's visual field. Attending a hockey game was difficult, as the brightly dressed

players left streaks of their images against the white of the ice for seconds at a time. The patient also described the false perception of movement in stable objects, usually in his peripheral visual fields, halos around objects, and positive and negative afterimages. Other symptoms included mild depression, daily bitemporal headache, and a loss of concentration in the last year.

The visual syndrome had gradually emerged over the last 3 months following experimentation with the hallucinogenic drug LSD-25 on three separate occasions. He feared he had sustained "brain damage" from the drug experience. He denied using any other agents. He had smoked marijuana twice a week for 7 months at age 17.

The patient had consulted two ophthalmologists, who found no visual abnormality. A neurologist's examination also proved negative. A therapeutic trial of an anticonvulsant medication resulted in a 50 percent improvement in the patient's visual symptoms and remission of his depression.

Hallucinogen Intoxication Delirium

Hallucinogen intoxication delirium is a relatively rare disorder beginning during intoxication in those who have ingested pure hallucinogens. An estimated 25 percent of all PCP-related emergency room patients may meet the criteria for hallucinogen intoxication delirium. Hallucinogens are often mixed with other substances, however, and those other substances or the subsequent drug–drug interactions can also cause delirium.

Hallucinogen-Induced Psychotic Disorders

If a patient using a hallucinogen has psychotic symptoms and inadequate reality testing, a diagnosis of a hallucinogen-induced psychotic disorder may be warranted. The course of this can be variable. Occasionally, a protracted psychotic episode is difficult to distinguish from a classic psychosis, such as from schizophrenia. Whether a chronic psychosis after drug ingestion is the result of drug ingestion, is unrelated, or is a combination of both the drug ingestion and predisposing factors is currently unanswerable. In some cases, however, the person had some predisposing disorder, such as schizoid

personality disorder.

A 22-year-old photography student presented to the hospital with an inappropriate mood and bizarre thinking. She had no prior psychiatric history. Nine days before admission, she ingested one or two psilocybin mushrooms. Following the immediate ingestion, the patient began to giggle. She then described euphoria, which progressed to auditory hallucinations and belief in the ability to broadcast her thoughts on the media. Two days later, she repeated the ingestion and continued to exhibit psychotic symptoms to the day of admission. When examined, she heard voices telling her she could be president and reported the sounds of "lambs crying." She continued to giggle inappropriately, bizarrely turning her head from side to side ritualistically. She continued to describe euphoria, but with an intermittent sense of hopelessness in a context of thought blocking. Her self-description was "feeling lucky." She received haloperidol, 10 mg twice a day, benztropine 1 mg three times a day, and lithium carbonate 300 mg twice a day. On this regimen, her psychosis improved after 5 days.

Hallucinogen-Induced Mood Disorder

Unlike cocaine-induced mood disorder and amphetamine-induced mood disorder, in which the symptoms are somewhat predictable, mood disorder symptoms accompanying hallucinogen abuse can vary. Abusers may experience manic-like symptoms with grandiose delusions or depression-like feelings and ideas or mixed symptoms. As with the hallucinogen-induced psychotic disorder symptoms, the symptoms of hallucinogen-induced mood disorder usually resolve after elimination from the body.

Hallucinogen-Induced Anxiety Disorder

Hallucinogen-induced anxiety disorder also varies in its symptom pattern, but few data about symptom patterns are available. Anecdotally, emergency department physicians who treat these patients frequently find that the syndrome resembles panic disorder. Anxiety is probably the most common symptom causing a PCP-intoxicated person to seek help in an emergency

room.

Unspecified Hallucinogen-Related Disorder

When a patient with a hallucinogen-related disorder does not meet the criteria for any of the standard hallucinogen-related disorders, this diagnosis may apply. An example would be a withdrawal syndrome associated with a hallucinogen, which has been occasionally reported, although DSM-5 does not include this diagnosis.

TREATMENT

Hallucinogen Intoxication

The most necessary treatment is reassurance and supportive care. Patients experiencing intense and unpleasant hallucinogen intoxication can be helped by a quiet environment, verbal reassurance, and the passage of time. More rapid relief of severe anxiety is likely after oral administration of 20 mg of diazepam or a parenteral benzodiazepine if oral use is not practical. Anxiety and other symptoms generally diminish within 20 minutes of medication administration, compared to hours with only psychological and environmental support; however, perceptual symptoms may persist. Patients may need gentle restraint if they present a danger to themselves or others, but clinicians should avoid restraints if possible. Antipsychotic medications, particularly if given at excessive doses, may worsen symptoms and are best avoided unless the diagnosis remains unclear and the behavior is unmanageable. The marketing of lower doses of LSD and a more sophisticated approach to the treatment of casualties by drug users themselves have combined to reduce the appearance of this once-common disorder in psychiatric treatment facilities.

Phencyclidine. Treatment of PCP intoxication aims to reduce systemic PCP levels and to address significant medical, behavioral, and psychiatric issues. For intoxication and PCP-induced psychotic disorder, although the resolution of current symptoms and signs is paramount, the long-term goal of treatment is to prevent relapse to PCP use. PCP levels can fluctuate over many hours or even days, especially after oral administration. A prolonged

period of clinical observation is, therefore, mandatory before concluding that no severe or life-threatening complications will ensue.

Trapping of ionized PCP in the stomach has led to the suggestion of continuous nasogastric suction as a treatment for PCP intoxication. This strategy, however, can be needlessly intrusive and can induce electrolyte imbalances. The preferred treatment is to administer activated charcoal, which binds PCP and diminishes its toxic effects in animal studies.

Trapping of ionized PCP in urine has led to the suggestion of urinary acidification as an aid to drug elimination. This strategy, however, may be ineffective and is potentially dangerous. The urine only excretes a small portion of PCP, metabolic acidosis itself carries significant risks, and acidic urine can increase the risk of renal failure secondary to rhabdomyolysis.

Hemodialysis and hemoperfusion are also ineffective, given the substantial volume of distribution of PCP.

No drug is known to function as a direct PCP antagonist. Any compound binding to the PCP receptor, located within the ion channel of the NMDA receptor, would block NMDA receptor-mediated ion fluxes, as PCP does. NMDA receptor mechanisms predict that pharmacologic strategies promoting NMDA receptor activation (e.g., administration of a glycine site agonist drug) would promote rapid dissociation of PCP from its binding sites. To date, there have been no clinical trials of NMDA agonists for PCP or ketamine intoxication in humans.

Because PCP disrupts sensory input, environmental stimuli can cause unpredictable, exaggerated, distorted, or violent reactions. A cornerstone of treatment, therefore, is to minimize sensory inputs. Patients should be evaluated and treated in a quiet and calm environment. Precautionary physical restraint is recommended by some authorities, with the risk of rhabdomyolysis from struggling against the restraints balanced by the avoidance of violent or disruptive behavior. Both antipsychotics and benzodiazepines are useful as sedatives, and neither is demonstrably superior. As PCP is an anticholinergic at high doses, drugs with anticholinergic properties (including some antipsychotics) should be avoided.

Hallucinogen-Persisting Perception Disorder. Treatment for hallucinogen-persisting perception disorder is palliative. The first step in the process is to identify the disorder; it is not uncommon for the patient to

consult several specialists before receiving a diagnosis. Pharmacologic approaches include long-acting benzodiazepines, such as clonazepam and, to a lesser extent, anticonvulsants, including valproic acid and carbamazepine. No drug is entirely adequate. Antipsychotics should only be used for psychotic symptoms because their side effects could exacerbate symptoms.

The second dimension of treatment is behavioral. We should instruct the patient to avoid gratuitous stimulation in the form of OTC drugs, caffeine, and alcohol, and avoidable physical and emotional stressors. Marijuana smoke is a particularly strong intensifier of the disorder, even when passively inhaled.

Finally, three comorbid conditions are associated with hallucinogen-persisting perception disorder: panic disorder, major depression, and alcohol use disorder. All these conditions require primary prevention and early intervention.

Hallucinogen-Induced Psychosis. Treatment of hallucinogen-induced psychosis does not differ from conventional treatment for other psychoses. In addition to antipsychotic medications, several agents are reportedly effective, including lithium carbonate, carbamazepine, and electroconvulsive therapy. Antidepressant drugs, benzodiazepines, and other anticonvulsants may have a role as well. Unlike schizophrenia, patients with this disorder lack negative symptoms—they have positive symptoms of psychosis but can still relate well to the psychiatrist. Also important are supportive, educational, and family therapies. The goals of treatment are the control of symptoms, minimal use of hospitals, daily work, the development and preservation of social relationships, and the management of comorbid illnesses such as alcohol use disorder.

EPIDEMIOLOGY

People have used hallucinogens for thousands of years, and drug-induced hallucinogenic states have been part of social and religious rituals. The discovery of LSD in 1943 increased the use and misuse of hallucinogens because it is easy and inexpensive to make such synthetic hallucinogens. They are also more potent than their botanical counterparts, and the development of synthetic hallucinogens is mostly responsible for the

psychiatric disorders associated with these drugs.

The incidence of hallucinogen use has had two notable periods of increase. Between 1965 and 1969, there was a 10-fold increase in the estimated annual number of initiates. This increase was driven primarily by the use of LSD. The second peak in first-time hallucinogen use occurred from around 1992 until 2000, fueled mainly by ecstasy (MDMA). Decreases in the initiation of both LSD and ecstasy were evident between then and 2013, coinciding with an overall drop in hallucinogen incidence from 1.6 to 1.1 million.

The NSDUH found that approximately 0.5 percent of persons age 12 years or older reported current use of hallucinogens. In 2016, the NSDUH added questions about the use of ketamine, DMT/AMT (α-methyltryptamine)/"Foxy" (5-methoxy-N,N-dimethyltryptamine [5-MeO-DMT]), and *Salvia divinorum*; for this reason, it is not possible to compare current rates of use with past rates. The lifetime prevalence of hallucinogen use disorder is about 0.6 to 1.7 percent. Approximately 5 percent of those with a lifetime history of hallucinogen use may develop hallucinogen dependence.

Hallucinogen use is most common among young (15 to 35 years of age) white men. About 60 percent of hallucinogen users are men. Persons 26 to 34 years of age show the highest use of hallucinogens, with 16 percent having used a hallucinogen at least once. Persons 18 to 25 years of age have the highest recent use of a hallucinogen. The ratio of whites to blacks who have used a hallucinogen is 2:1; the white to Hispanic ratio is about 1.5:1.

Cultural factors influence the use of hallucinogens; their use in the western United States is significantly higher than in the southern United States.

Hallucinogen use is associated with less morbidity and less mortality than many other substances of abuse. For example, one study found that only 1 percent of substance-related emergency department visits were related to hallucinogens, compared with 40 percent for cocaine-related problems. Of persons visiting the emergency department for hallucinogen-related reasons, however, more than 50 percent were younger than 20 years of age. Currently, there may be a resurgence in the popularity of hallucinogens among youths.

Phencyclidine

Phencyclidine and some related substances are relatively easy to synthesize in

illegal laboratories and relatively inexpensive to buy on the street. The variable quality of the laboratories, however, results in a range of potency and purity. PCP use varies most markedly with geography. Most users of PCP also use other substances, particularly alcohol, but also opiates, opioids, marijuana, amphetamines, and cocaine. Marijuana products often include PCP, with severe untoward effects on users. The actual rate of PCP use disorder is not known, but PCP is associated with 3 percent of substance abuse deaths and 32 percent of substance-related emergency department visits nationally.

PATHOLOGY

Neuropharmacology

LSD is a reasonable prototype for this group, although there is considerable variation. LSD probably acts on the serotonergic system—but exactly how, and in what direction, is not clear. Data at this time suggest that LSD acts as a partial agonist at postsynaptic serotonin receptors.

Most hallucinogens are well absorbed after oral ingestion, although some are inhaled, smoked, or injected. Tolerance to hallucinogens develops rapidly and is virtually complete after 3 or 4 days of continuous use. Tolerance also reverses quickly, usually in 4 to 7 days. Most people do not experience physical dependence or withdrawal, but they can develop psychological dependence, especially if they find the hallucinations pleasant or useful.

Phencyclidine and Ketamine. PCP and ketamine antagonize the NMDA subtype of glutamate receptors. PCP binds to a site within the NMDA-associated calcium channel and prevents the influx of calcium ions. PCP also activates the dopaminergic neurons of the VTA, which project to the cerebral cortex and the limbic system. Activation of these neurons is usually involved in mediating the reinforcing qualities of PCP.

Tolerance for the effects of PCP occurs in humans, although physical dependence generally does not occur. In animals that are administered more PCP per pound for longer times than most humans, PCP does induce physical dependence. Physical withdrawal in humans is rare, likely because the doses and durations are much lower. Although the physical dependence on PCP is

rare in humans, psychological dependence on both PCP and ketamine is common.

PCP usually comes from illicit laboratories, so impurities are likely. One such contaminant is 1-piperidenocyclohexane carbonitrite, which releases hydrogen cyanide in small quantities when ingested. Another contaminant is piperidine, which can be recognized by its strong, fishy odor.

▲ 4.10 Inhalant-Related Disorders

Inhalant drugs (also called *volatile substances* or *solvents*) are volatile hydrocarbons that vaporize to gaseous fumes at room temperature and are inhaled through the nose or mouth to enter the bloodstream via the transpulmonary route. These compounds are commonly found in many household products and are divided into four commercial classes: (1) solvents for glues and adhesives; (2) propellants (e.g., for aerosol paint sprays, hair sprays, and shaving cream); (3) thinners (e.g., for paint products and correction fluids); and (4) fuels (e.g., gasoline, propane). These drugs likely share some similar pharmacologic properties despite their chemical differences.

CLINICAL FEATURES

Persons, especially adolescents, like to inhale these products for their intoxicating effect. Inhalants are associated with several problems, including conduct disorder, mood disorders, suicidality, and physical abuse or neglect and sexual abuse. In some cases, early time-limited use of inhalants may signal a lifelong problem with externalizing behaviors and risk-taking propensity. A smaller subgroup uses inhalants chronically, and such use can cause multiple sequelae, including significant behavioral and organ pathology from the drugs' toxicity.

In small initial doses, inhalants can be disinhibiting and produce feelings of euphoria and excitement as well as pleasant floating sensations, the effects for which persons presumably use the drugs. High doses of inhalants can cause psychological symptoms of fearfulness, sensory illusions, auditory and visual hallucinations, and distortions of body size. The neurologic symptoms

can include slurred speech, decreased speed of talking, and ataxia. Long-term use can be associated with irritability, emotional lability, and impaired memory.

Tolerance for the inhalants does develop for some users; a withdrawal syndrome can accompany the cessation of inhalant use. The withdrawal syndrome does not occur frequently; when it does, it includes sleep disturbances, irritability, jitteriness, sweating, nausea, vomiting, tachycardia, and (sometimes) delusions and hallucinations.

DIAGNOSIS

The DSM-5 describes several disorders related to inhalants, including inhalant use disorder, inhalant intoxication, inhalant intoxication delirium, inhalant-induced neurocognitive disorder, inhalant-induced psychotic disorder, inhalant-induced mood and anxiety disorders, and other inhalant-induced disorders. The DSM-5 excludes anesthetic gases (e.g., nitrous oxide and ether) and short-acting vasodilators (e.g., amyl nitrite) from the inhalant-related disorders, these are classified within the generic category of "other (or unknown) substance-related disorders." ICD-10 follows a similar approach.

Inhalant Use Disorder

Most persons probably use inhalants for a short time without developing dependence or abuse. Nonetheless, dependence and abuse of inhalants occur.

Inhalant Intoxication

The diagnostic criteria for inhalant intoxication specify the presence of maladaptive behavioral changes and at least two physical symptoms. People who become intoxicated on inhalants may have apathy, diminished social and occupational functioning, impaired judgment, and impulsive or aggressive behavior. They can also have nausea, anorexia, nystagmus, depressed reflexes, and diplopia. With high doses and long exposures, a user's neurologic status can progress to stupor and unconsciousness, and a person may later be amnestic for the period of intoxication. Clinicians can sometimes identify a recent user of inhalants by rashes around the patient's nose and mouth; unusual breath odors; the residue of the inhalant substances

on the patient's face, hands, or clothing; and irritation of the patient's eyes, throat, lungs, and nose. The disorder can be chronic, as in the following case.

A 16-year-old single Hispanic female came to a university substance-treatment program for evaluation. The patient had been convicted for auto theft, using a weapon, and being out of control by her family. By age 15, she had regularly been using inhalants and drinking alcohol heavily. She had tried typewriter-erasing fluid, bleach, tile cleaner, hairspray, nail polish, glue, and gasoline, but preferred spray paint. She had sniffed paint many times each day for about 6 months at age 15, using a maximum of eight paint cans per day. The patient said, "It blacks out everything." Sometimes she had lost consciousness, and she believed that the paint had impaired her memory and made her "dumb." (Courtesy of Thomas J. Crowley, M.D.)

Inhalant Intoxication Delirium. The inhalants can directly cause delirium. Also, their interactions with other substances or the hypoxia caused by their use can cause delirium. If the delirium results in severe behavioral disturbances, short-term treatment with a dopamine receptor antagonist, such as haloperidol, may be necessary. Clinicians should avoid benzodiazepines because of the possibility of increasing the patient's respiratory depression.

Inhalant-Induced Neurocognitive Disorder. Inhalant-induced neurocognitive disorder, as with delirium, may result from the neurotoxic effects of the inhalants themselves, the neurotoxic effects of the metals (e.g., lead) commonly used in inhalants; or the impact of frequent and prolonged periods of hypoxia. Dementia caused by inhalants is likely to be irreversible in all but the mildest cases.

Inhalant-Induced Psychotic Disorder. Clinicians can specify hallucinations or delusions as predominant symptoms. Paranoid states are probably the most common psychotic syndromes during inhalant intoxication.

Inhalant-Induced Mood Disorder and Inhalant-Induced Anxiety

Disorder. Inhalant-induced mood disorder and inhalant-induced anxiety disorder allow the classification of inhalant-related disorders characterized by prominent mood and anxiety symptoms. Depressive disorders are the most common mood disorders associated with inhalant use, and panic disorders and generalized anxiety disorder are the most common anxiety disorders.

Other Inhalant-Induced Disorders. Other Inhalant-Induced Disorder is the recommended DSM-5 diagnosis for inhalant-related disorders that do not fit into one of the diagnostic categories discussed earlier.

TREATMENT

Inhalant intoxication, as with alcohol intoxication, usually requires no medical attention and resolves spontaneously. However, possible effects of the intoxication, such as coma, bronchospasm, laryngospasm, cardiac arrhythmias, trauma, or burns, need treatment. Otherwise, care primarily involves reassurance, quiet support, and attention to vital signs and level of consciousness. Sedative drugs, including benzodiazepines, are contraindicated because they worsen inhalant intoxication.

No established treatment exists for the cognitive and memory problems of inhalant-induced neurocognitive disorder. Severely deteriorated, inhalant-dependent, homeless adults could benefit from street outreach and extensive social service. Patients may require comprehensive support within their families or in foster or domiciliary care.

The course and treatment of inhalant-induced psychotic disorder are like those of inhalant intoxication. The disorder is brief, lasting a few hours to (at most) a very few weeks beyond the intoxication. Vigorous treatment of such life-threatening complications as respiratory or cardiac arrest is indicated, together with conservative management of the intoxication itself. Symptoms such as confusion, panic, and psychosis require special attention to patient safety. Severe agitation may require cautious control with haloperidol (5 mg intramuscularly per 70 kg body weight). Clinicians should avoid sedative drugs because they may aggravate psychosis. Inhalant-induced anxiety and mood disorders may precipitate suicidal ideation, and we should carefully evaluate patients for that possibility. Antianxiety medications and antidepressants are not useful in the acute phase of the disorder; they may be

of use in cases of coexisting anxiety or depressive illness.

Day Treatment and Residential Programs

Day treatment and residential programs have been used successfully, especially for adolescent abusers with combined substance use disorders and other psychiatric disorders. Treatment addresses the comorbid state, which, in most cases, is conduct disorder or, in some other cases, may be ADHD, major depressive disorder, persistent depressive disorder (dysthymia), and PTSD. Treatment for abuse or neglect, both very common in these patients, is also important. Both group and individual therapy that are behaviorally oriented are employed, with immediate rewards for progress toward objectively defined goals in treatment and consequences for lapses to previous behaviors. Patients attend on-site schools with special education teachers, together with planned recreational activities, and the programs provide birth control consultations. The patients' families, often very chaotic, are engaged in modifications of structural family therapy or multisystemic therapy, both of which have reasonable empirical support. Participation in 12-step programs is required. Treatment interventions are coordinated carefully with interventions by community social workers and probation officers. We can monitor progress with urine and breath samples analyzed for alcohol and other drugs at intake and frequently during treatment.

Treatment usually lasts 3 to 12 months. Table 4-45 lists some goals for treatment.

EPIDEMIOLOGY

Inhalant substances are readily available, legal, and inexpensive. These three factors contribute to the high use of inhalants among poor persons and young persons. Approximately 0.2 percent of persons age 12 and older in the United States are current users of inhalants. Adolescents (ages 12 to 17) are more likely to use inhalants than individuals in other age groups. According to the NSDUH, in 2016, only 0.2 percent of adults were using inhalants. In contrast, twice to three times as many adolescents were using inhalants. In adolescents, males and females use inhalants almost equally (with a slight increase in use for females), while in adults, inhalant use is rare in females.

Table 4-45
Goals of Treatment for Inhalant Disorder

Has practiced a plan to stay abstinent

Is showing fewer antisocial behaviors

Has a plan to continue any needed psychiatric treatment (e.g., treatment for comorbid depression)

Has a plan to live in a supportive, drug-free environment

Is interacting with the family in a more productive way

Is working or attending school

Is associating with drug-free, nondelinquent peers

Inhalant use among adolescents may be most common in those whose parents or older siblings use illegal substances, or among adolescents who have experienced childhood trauma or maltreatment. Inhalant use among adolescents is also associated with an increased likelihood of conduct disorder or antisocial personality disorder.

Pathology

Neuropharmacology. Inhalants most used by American adolescents are gasoline, glue (which usually contains toluene), spray paint, solvents, cleaning fluids, and assorted other aerosols. Sniffing vapor through the nose or huffing (taking deep breaths) through the mouth leads to transpulmonary absorption with very rapid drug access to the brain. Breathing through a solvent-soaked cloth, inhaling fumes from a glue-containing bag, huffing vapor sprayed into a plastic bag, or breathing vapor from a gasoline can are common. Approximately 15 to 20 breaths of 1 percent gasoline vapor produce several hours of intoxication. Inhaled toluene concentrations from a glue-containing bag may reach 10,000 ppm, and people may inhale fumes from several tubes each day. By comparison, one study of just 100 ppm of toluene showed that a 6-hour exposure produced a temporary neuropsychological performance decrement of approximately 10 percent.

Inhalants generally act as a CNS depressant. Tolerance for inhalants can develop, although withdrawal symptoms are usually relatively mild.

Inhalants are rapidly absorbed through the lungs and quickly delivered to the brain. The effects appear within 5 minutes and can last for 30 minutes to several hours, depending on the inhalant substance and the dose. The concentrations of many inhalant substances in the blood increase when combined with alcohol, perhaps because of the competition for hepatic enzymes.

Although about one-fifth of an inhalant substance is excreted unchanged by the lungs, the liver metabolizes the remainder. Inhalants are detectable in the blood for 4 to 10 hours after use, and blood samples should be taken in the emergency department when inhalant use is suspected.

Much like alcohol, inhalants have specific pharmacodynamic effects that are not well understood. Because their effects are generally similar and additive to the effects of other CNS depressants (e.g., ethanol, barbiturates, and benzodiazepines), some investigators have suggested that inhalants operate by enhancing the GABA system. Other investigators have suggested that inhalants work through membrane fluidization, which may also be a pharmacodynamic effect of ethanol.

Organ Pathology and Neurologic Effects. Inhalants are associated with many potentially dangerous adverse effects. The most serious of these is death, which can result from respiratory depression, cardiac arrhythmias, asphyxiation, aspiration of vomitus, or accident or injury (e.g., driving while intoxicated with inhalants).

Placing an inhalant-soaked rag and one's head into a plastic bag, a standard procedure for inhalant users can cause coma and suffocation.

Chronic inhalant users may have numerous neurologic problems. Computed tomography (CT) and magnetic resonance imaging (MRI) reveal diffuse cerebral, cerebellar, and brainstem atrophy with white matter disease, a leukoencephalopathy. Single-photon emission CT (SPECT) of former solvent-abusing adolescents showed both increases and decreases in blood flow in different cerebral areas. Several studies of house painters and factory workers exposed to solvents for long periods also have found evidence of brain atrophy on CT scans, with decreased CBF.

Neurologic and behavioral signs and symptoms can include hearing loss, peripheral neuropathy, headache, paresthesias, cerebellar signs, persisting motor impairment, parkinsonism, apathy, poor concentration, memory loss,

visual–spatial dysfunction, impaired processing of linguistic material, and lead encephalopathy. White matter changes, or pontine atrophy on MRI, have been associated with worse intelligence quotient (IQ) test results. The combination of organic solvents with high concentrations of copper, zinc, and heavy metals can cause brain atrophy, temporal lobe epilepsy, decreased IQ, and a variety of EEG changes.

Other serious adverse effects associated with long-term inhalant use include irreversible hepatic disease or renal damage (tubular acidosis) and permanent muscle damage associated with rhabdomyolysis. Additional adverse effects include cardiovascular and pulmonary symptoms (e.g., chest pain and bronchospasm) as well as GI symptoms (e.g., pain, nausea, vomiting, and hematemesis). There are several clinical reports of *toluene embryopathy,* with signs such as those of fetal alcohol syndrome. These include low birth weight, microcephaly, shortened palpebral fissures, small face, low-set ears, and other dysmorphic signs. These babies reportedly develop slowly, show hyperactivity, and have cerebellar dysfunction. No convincing evidence indicates, however, that toluene, the best-studied inhalant, produces genetic damage in somatic cells.

▲ 4.11 Anabolic-Androgenic Steroid Use

The anabolic-androgenic steroids (AAS) are a family of hormones that includes testosterone, the natural male hormone, which, together with numerous synthetic analogs of testosterone, have been developed over the last 70 years (Table 4-46). These drugs exhibit various degrees of anabolic (muscle building) and androgenic (masculinizing) effects; none of these drugs display purely anabolic effects in the absence of androgenic effects. It is important not to confuse the AAS (testosterone-like hormones) with corticosteroids (cortisol-like hormones such as hydrocortisone and prednisone).

Table 4-46
Examples of Commonly Used Anabolic Steroids

Compounds Usually Administered Orally Department:
Fluoxymesterone (Halotestin, Android-F, Ultandren)
Methandienone (formerly called Methandrostenolone; Dianabol)
Methyltestosterone (Android, Testred, Virilon)
Mibolerone (Cheque Drops[a])
Oxandrolone (Anavar)
Oxymetholone (Anadrol, Hemogenin)
Mesterolone (Mestoranum, Proviron)
Stanozolol (Winstrol)

Compounds Usually Administered Intramuscularly:
Nandrolone decanoate (Deca-Durabolin)
Nandrolone phenpropionate (Durabolin)
Methenolone enanthate (Primobolan Depot)
Boldenone undecylenate (Equipoise[a])
Stanozolol (Winstrol-V[a])
Testosterone esters blends (Sustanon, Sten)
Testosterone cypionate
Testosterone enanthate (Delatestryl)
Testosterone propionate (Testoviron, Androlan)
Testosterone undecanoate (Andriol, Restandol)
Trenbolone acetate (Finajet, Finaplix[a])
Trenbolone hexahydrobencylcarbonate (Parabolan)

[a]Veterinary compound.

Note: Many of the brand names listed in this table are from other countries, but they are included because of the widespread illicit use of foreign steroid preparations in the United States.

Corticosteroids are hormones secreted by the adrenal gland, rather than by the testes. Corticosteroids have no muscle-building properties and, hence, little abuse potential; they treat many inflammatory conditions such as poison ivy or asthma. AAS, by contrast, have only limited legitimate medical applications, such as in the treatment of hypogonadal men and diseases associated with muscle wasting, such as acquired immunodeficiency syndrome (AIDS) and cancer. AAS, however, are widely used illicitly,

especially by boys and young men seeking to gain increased muscle mass and strength, either for athletic purposes or to improve personal appearance.

AAS do not have a diagnostic category in the DSM-5; instead, it is coded as one of the other or unknown substance-related disorders. ICD-10 includes the diagnosis in the category "Abuse of non–dependence-producing substances," which also includes antacids, herbal remedies, and vitamins.

CLINICAL FEATURES AND DIAGNOSIS

Steroids may initially induce euphoria and hyperactivity. After relatively short periods, however, their use can become associated with less desirable symptoms. Studies have reported that 2 to 15 percent of anabolic steroid abusers experience hypomanic or manic episodes, and a smaller percentage may have psychotic symptoms. Also disturbing is a correlation between steroid abuse and violence ("roid rage" in the parlance of users). Steroid abusers with no record of antisocial behavior or violence have committed murders and other violent crimes.

Steroids are addictive substances. When abusers stop taking steroids, they can become depressed, anxious, and concerned about the physical state of their bodies. Some male and female weight lifters may have muscle dysmorphia, a form of body dysmorphic disorder in which the individual feels that he or she is not sufficiently muscular and lean. There are some similarities between an athlete's and a patient with anorexia nervosa's self-perception; to an observer, both groups seem to distort the realistic assessment of the body.

Iatrogenic addiction is a consideration given the increasing number of geriatric patients who are receiving testosterone from their physicians in an attempt to increase libido and reverse some aspects of aging.

Mr. A is a 26-year-old single man. He is 69 in tall and presently weighs 204 lb, with a body fat of 11 percent. He reports that he began lifting weights at age 17, at which time he weighed 155 lb. About 2 years after beginning his weight lifting, he began taking AAS, which he obtained through a friend at his gymnasium. His first "cycle" (course) of AAS, lasting for 9 weeks, involved methandienone, 30 mg a day, orally, and

testosterone cypionate, 600 mg a week, intramuscularly. During these 9 weeks, he gained 20 lb of muscle mass. He was so pleased with these results that he took five further cycles of AAS over the next 6 years. During his most ambitious cycle, approximately 1 year ago, he used testosterone cypionate, 600 mg/wk; nandrolone decanoate, 400 mg a week; stanozolol, 12 mg a day; and oxandrolone, 10 mg a day.

During each of the cycles, Mr. A has noted euphoria, irritability, and grandiose feelings. These symptoms were most prominent during his most recent cycle when he felt "invincible." During this cycle, he also noted a decreased need for sleep, racing thoughts, and a tendency to spend excessive amounts of money. For example, he impulsively purchased a $2,700 stereo system when he could not afford to spend more than $500. He also became uncharacteristically irritable with his girlfriend, and on one occasion, put his fist through the side window of her car during an argument, an act inconsistent with his normally mild-mannered personality. After this cycle of AAS ended, he became mildly depressed for about 2 months.

Mr. A has used several drugs to lose weight in preparation for bodybuilding contests. These include ephedrine, amphetamine, triiodothyronine, and thyroxin. Recently, he has also begun to use the opioid agonist–antagonist nalbuphine intravenously (IV) to treat muscle aches from weight lifting. He also used oral opioids, such as controlled-release oxycodone, at least once a week. He uses oral opioids sometimes to treat muscle aches, but often to get high. He reports that the use of nalbuphine and other opioids is widespread among other AAS users of his acquaintance.

Mr. A exhibits characteristic features of muscle dysmorphia. He regularly checks his appearance, including his reflection in windows or even in the back of a spoon. He becomes anxious if he misses even one day of working out at the gym, and acknowledges that his preoccupation with weight lifting has cost him both social and occupational opportunities. Although he has a 48-in chest and 19-in biceps, he has frequently declined invitations to go to the beach or a swimming pool for fear that he would look too small when seen in a bathing suit. He is anxious because he has lost some weight since the end of his previous cycle of AAS and is eager to resume another cycle of AAS soon.

Anabolic Steroid–Induced Mood Disorders

Table 4-47 lists some typical symptoms associated with anabolic steroid use. Although athletes using these drugs have long recognized that syndromes of anger and irritability could be associated with AAS use, the scientific literature did not recognize this syndrome until the late 1980s and 1990s. Since then, a series of observational field studies of athletes have suggested that some AAS users develop prominent hypomanic or even manic symptoms during AAS use.

A possible severe consequence of AAS-induced mood disorders may be violent or even homicidal behavior. Several published reports have anecdotally described individuals with no apparent history of psychiatric disorder, no criminal record, and no history of violence, who committed violent crimes, including murder, while under the influence of AAS. Although a causal link is difficult to establish in these cases, lawyers have presented evidence of AAS use in forensic settings as a possible mitigating factor in criminal behavior.

Table 4-47
Symptoms Associated with Anabolic Steroid Use

Euphoria
Hyperactivity
Irritability
Anger
Aggressiveness
Hypomania
Mania
Violent behavior ("Roid Rage")
Homicidal behavior
Suicide
Psychosis
Withdrawal symptoms: somatization, depression

Depressive syndromes induced by AAS have occurred, and suicide is a risk. A brief and self-limited syndrome of depression occurs upon AAS withdrawal, probably as a result of the depression of the hypothalamic–pituitary–gonadal axis after exogenous AAS administration.

Anabolic Steroid–Induced Psychotic Disorder

Psychotic symptoms are rare in association with anabolic steroid use, but they occasionally occur, primarily in individuals who were using the equivalent of more than 1,000 mg of testosterone a week. Usually, these symptoms consist of grandiose or paranoid delusions, generally occurring in the context of a manic episode, although occasionally occurring in the absence of a frank manic syndrome. In most cases reported, psychotic symptoms have disappeared promptly (within a few weeks) after the discontinuation of the offending agent, although temporary treatment with antipsychotic agents was sometimes required.

Other Anabolic Steroid–Related Disorders

Symptoms of anxiety disorders, such as panic disorder and social phobia, can occur during AAS use. AAS use may serve as a "gateway to the use of opioid agonists or antagonists, such as nalbuphine, or to use of frank opioid agonists, such as heroin."

TREATMENT

Abstinence is the treatment goal of choice for patients manifesting AAS use disorders. To the extent that users of AAS abuse other addictive substances (including alcohol), traditional treatment approaches for substance-related disorders may be used. Nevertheless, AAS users may differ from other addicted patients in several ways that have implications for treatment. First, the euphorigenic and reinforcing effects of AAS may only become apparent after weeks or months of use in conjunction with intensive exercising. When compared with immediately and passively reinforcing drugs, such as cocaine, heroin, and alcohol, AAS use may entail more delayed gratification. Second, AAS users may manifest a more significant commitment to culturally endorsed values of physical fitness, success, victory, and goal directedness

than users of other illicit drugs. Finally, AAS users are often preoccupied with their physical attributes and may rely excessively on these attributes for self-esteem. Treatment, therefore, depends on a therapeutic alliance and a thorough and nonjudgmental understanding of the patient's values and motivations for using AAS.

Though there are no controlled trials of treatment for AAS-related disorders, following the generally recommended approaches for the related idiopathic syndrome may be appropriate. For example, muscle dysmorphia may improve with CBTs or the use of SSRIs.

AAS Withdrawal

Supportive therapy and monitoring are essential for treating AAS withdrawal because suicidal depressions can occur. Hospitalization may be required when suicidal ideation is severe. Patients should be educated about the possible course of withdrawal and reassured that symptoms are time-limited and manageable. Clinicians should reserve antidepressant agents for patients whose depressive symptomatology persists for several weeks after AAS discontinuation and who likely have a comorbid depressive disorder. SSRIs are the preferred agents because of their favorable adverse effect profile and their effectiveness in a reported case series of treated AAS users with major depressive disorder. Physical withdrawal symptoms are not life threatening and do not ordinarily require pharmacotherapy. Nonsteroidal anti-inflammatory drugs (NSAIDs) may be useful to treat musculoskeletal pain and headaches. AAS-induced hypogonadism, including loss of libido, erectile dysfunction, and possible major depression, may begin during AAS withdrawal and can sometimes be prolonged, requiring treatment by an endocrinologist. Patients with AAS-induced hypogonadism may benefit from physiologic exogenous doses of testosterone, gradually tapered over time, as well as clomiphene (to restore hypothalamic–pituitary–testicular [HPT] function) and HCG (to stimulate the testis to resume production of testosterone and spermatozoa).

EPIDEMIOLOGY

It is difficult to estimate the lifetime prevalence of illicit AAS use in the United States because most available data rely on anonymous surveys of

students, particularly students of high school age. There are two serious problems with the use of these data. First, the median age of onset of AAS use, both in the United States and other countries, is approximately 23 years of age—older than for any other major category of illicit drugs. Second, anonymous surveys are vulnerable to serious errors in the opposite direction as a result of false-positive responses to the survey questions about "steroids." When asking students a typical survey question, such as whether they have used "steroid pills or shots without a doctor's prescription," they may falsely respond in the affirmative when in fact they have taken only corticosteroids, or have purchased nutritional supplements OTC that they mistakenly believed were steroids. After allowing for these sources of error, the true prevalence of AAS in high school girls is close to 0 percent and in boys about 1 percent. However, by adulthood, perhaps 3 to 4 percent of American men have used AAS at some time in their lives, and approximately 1.8 percent of American women have used AAS. In general, males are more likely to take AAS than females, and athletes are more likely to take AAS than nonathletes.

The current high rates of steroid use among younger individuals appear to represent an essential shift in the epidemiology of steroid use. In the 1970s, most users were competition bodybuilders or other elite athletes. Since then, however, it appears that an increasing number of young men, and occasionally even young women may use these drugs purely to enhance personal appearance rather than for any athletic purpose.

PATHOLOGY

Pharmacology

All steroid drugs—including AAS, estrogens, and corticosteroids—are synthesized in vivo from cholesterol and resemble cholesterol in their chemical structure. Testosterone has a four-ring chemical structure containing 19 carbon atoms.

Average testosterone plasma concentrations for men range from 300 to 1,000 ng/dL. Generally, 200 mg of testosterone cypionate taken every 2 weeks restores physiologic testosterone concentrations in a hypogonadal male. A eugonadal male who initiates physiologic dosages of testosterone has

no net gain in testosterone concentrations because exogenously administered AAS shut down endogenous testosterone production via feedback inhibition of the hypothalamic–pituitary–gonadal axis. Consequently, illicit users take higher than therapeutic dosages to achieve supraphysiologic effects. The dose–response curve for anabolic effects may be logarithmic, which could explain why illicit users generally take 10 to 100 times the therapeutic dosages. Doses in this range usually require combinations of oral and injected AAS, which illicit AAS users often do. Transdermal testosterone, available by prescription for testosterone replacement therapy, may also be used.

Therapeutic Indications. The AAS are indicated primarily for testosterone deficiency (male hypogonadism), hereditary angioedema (a congenital skin disorder), and some rare forms of anemia caused by bone marrow or renal failure. Women may use AAS for metastatic breast cancer, osteoporosis, endometriosis, and adjunctive treatment of menopausal symptoms. However, these are not first-line treatments. In men, they have been used experimentally as a male contraceptive and for treating major depressive disorder and sexual disorders in eugonadal men. Recently, they have been used to treat wasting syndromes associated with AIDS. Controlled studies have also suggested that testosterone has antidepressant effects in some men infected with HIV with major depressive disorder and is also a supplementary (augmentation) treatment in some depressed men with low endogenous testosterone levels who are refractory to conventional antidepressants.

Adverse Reactions

The most common adverse medical effects of AAS involve the cardiovascular, hepatic, reproductive, and dermatologic systems.

The AAS produce an adverse cholesterol profile by increasing levels of low-density lipoprotein cholesterol and decreasing levels of high-density lipoprotein cholesterol. High-dose use of AAS can also activate hemostasis and increase blood pressure. Isolated case reports of myocardial infarction, cardiomyopathy, left ventricular hypertrophy, and stroke among users of AAS, including fatalities, have appeared.

Among the AAS-induced endocrine effects in men are testicular atrophy

and sterility, both usually reversible after discontinuing AAS, and gynecomastia, which may persist until surgical removal. In women, shrinkage of breast tissue, irregular menses (diminution or cessation), and masculinization (clitoral hypertrophy, hirsutism, and deepened voice) can occur. Masculinizing effects in women may be irreversible. Androgens taken during pregnancy could cause the masculinization of a female fetus. Dermatologic effects include acne and male pattern baldness. Abuse of AAS by children has led to concerns that AAS-induced premature closure of bony epiphyses could cause shortened stature. Other uncommon adverse effects include edema of the extremities caused by water retention, exacerbation of tic disorders, sleep apnea, and polycythemia.

ETIOLOGY

The primary reason for taking illicit AAS is to enhance either athletic performance or physical appearance. Taking AAS is reinforced because they can produce the athletic and physical effects that users desire, especially when combined with proper diet and training. Further reinforcement derives from winning competitions and from social admiration for physical appearance. AAS users also perceive that they can train more intensively for longer durations with less fatigue and with decreased recovery times between workouts.

Although the anabolic or muscle-building properties of AAS are important to those seeking to enhance athletic performance and physical appearance, psychoactive effects may also be valuable in the persistent and dependent use of AAS. Anecdotally, some AAS users report feelings of power, aggressiveness, and euphoria, which become associated with and can reinforce AAS taking.

▲ 4.12 Gambling Disorder

Although not related to a substance, gamblers share many features in common with other addictive disorders.

CLINICAL FEATURES

Pathologic gamblers often appear overconfident, somewhat abrasive, energetic, and free-spending. They often show apparent signs of personal stress, anxiety, and depression. They commonly have the attitude that money is both the cause of and the solution to all their problems. As their gambling increases, they may lie to obtain money and to continue gambling while hiding the extent of their gambling. They make no serious attempt to budget or save money. When without borrowing resources, they are likely to engage in antisocial behavior to obtain money for gambling. Their criminal behavior is typically nonviolent, such as forgery, embezzlement, or fraud, and they consciously intend to return or repay the money.

Complications include alienation from family members and acquaintances, the loss of life accomplishments, suicide attempts, and association with fringe and illegal groups. Arrest for nonviolent crimes may lead to imprisonment.

DIAGNOSIS

DSM-5 refers to this disorder as gambling disorder, whereas ICD-10 calls it pathologic gambling; Table 4-48 lists their comparative approaches to the disorder.

Previous editions of the DSM include pathologic gambling disorder in the impulse-control disorder category because of the patient's preoccupation or compulsion to gamble. However, the criteria for the disorder are more similar to substance-related disorders, given the compulsive behavior, tolerance, and withdrawal effects that develop. Substance use is often comorbid with gambling. Thus, in DSM-5, gambling disorder is included in the section on substance use and addictive disorders and is diagnosed as a non–substance-related disorder. ICD-10 continues to include it among the habit and impulse disorders, referring to it as pathologic gambling.

Gerry was a 35-year-old former auto dealership owner. Two of his uncles were compulsive gamblers, and his paternal grandfather had major depressive disorder. He played poker and had been a racecourse habitué since the age of 15 years. He had dropped out of college after a few months and became a car sales representative. Soon he was promoted to showroom manager and then went out on his own. By age 32 years, he

was a multimillionaire owner of a dealership chain, happily married with two children.

Gerry continued to gamble frequently. He was a successful weekend sports bettor, as well as a consistent winner at weekly gin rummy and poker games and occasional jaunts to Las Vegas and Atlantic City.

In the context of his wife giving birth to a stillborn child, Gerry started going to casinos more often, gradually increasing the size of bets at blackjack and craps. His sports wagers also escalated. His games at home gradually became boring—"there was zilch action." He began frequenting an illegal local poker parlor that featured high-stake action.

Over several years, Gerry slipped into a typical gambling spiral. He accumulated several million dollars in debts and lied to family and colleagues about his whereabouts. He raided his business and personal accounts, including his children's college funds, maxed out credit cards, and borrowed from loan sharks at exorbitant rates. He grew profoundly depressed and seriously thought of killing himself in a car crash so that his insurance would "take care of my family after I am gone."

Gerry's dire situation was unmasked when his Porsche was repossessed one Sunday morning. Initially, his wife threatened to divorce him. However, a wealthy relative intervened and bailed him out. He swore never to gamble again, entered Gamblers Anonymous, and within 2 months, resumed his frantic gambling.

Over the next decade, Gerry underwent four more episodes of recovery and relapse. His wife divorced him, he lost his dealerships, and he had to declare bankruptcy. Gerry finally enrolled in a pilot dual-diagnostic recovery program, where he was diagnosed with atypical bipolar disorder. His treatment included Gamblers Anonymous meetings, individual and family counseling, and pharmacotherapy with bupropion and lamotrigine.

Gerry eventually reconciled with his wife and family. He returned to selling cars, started living modestly, and continued to attend Gamblers Anonymous meetings regularly. However, he declared emphatically that he always considers himself one step away from becoming a "degenerate gambler" again. (Courtesy of Harvey Roy Greenberg, M.D.)

Table 4-48
Gambling Disorder

	Gambling Disorder	
Disorder	**DSM-5**	**ICD-10**
Diagnostic Name	Gambling Disorder	Pathologic Gambling
Duration	Symptoms present within a 12-month period	
Symptoms	• Needing higher stakes to achieve the same thrill • Becomes irritable when trying to stop • Unsuccessful attempts at reducing gambling • Preoccupation with thoughts about gambling • Gambling in response to distress • Gambling to recoup prior losses • Lies to hide gambling • Losses due to	Pattern of gambling that is dominant in the patient's life and resulting in adverse consequences in social, occupational, family, and other areas of life

	gambling: jobs, relationships, other opportunities • Borrows or steals money from others for gambling	
Required number of symptoms	Four or more of the above	
Psychosocial consequences of symptoms	Marked impairment and/or distress	
Exclusions	Manic episode	• Excessive gambling by manic patients • Gambling and betting NOS • Gambling in dissocial personality disorder
Course specifiers	**Episodic:** meets criteria more than once over time, separated by at least several months **Persistent:** continuous over several years **In early remission:** no symptoms for 3–12 mo **In sustained**	

	remission: no symptoms for >12 mo
Severity specifiers	Severity is measured by the number of symptoms present
	See DSM-5 for ranges

DIFFERENTIAL DIAGNOSIS

Social gambling is distinguished from pathologic gambling in that the former occurs with friends, on special occasions, and with predetermined acceptable and tolerable losses. Gambling that is symptomatic of a manic episode can usually be distinguished from pathologic gambling by the history of a marked mood change and the loss of judgment preceding the gambling.

Manic-like mood changes are frequent in pathologic gambling, but they always follow winning and are usually succeeded by depressive episodes because of subsequent losses. Persons with an antisocial personality disorder may have problems with gambling. When both disorders are present, clinicians should diagnose both.

COMORBIDITY

Significant comorbidity occurs between pathologic gambling and mood disorders (especially major depression and bipolarity) and other substance use and addictive disorders (notably, alcohol, stimulant, caffeine, and tobacco use disorders). Comorbidity also exists with ADHD (particularly in childhood), various personality disorders (notably, narcissistic, antisocial, and borderline personality disorders), and disruptive, impulse control, and conduct disorders. Although many pathologic gamblers have obsessive personality traits, full-blown OCD is uncommon in this group.

1. The winning phase, ending with a big win, equal to about a year's salary, which hooks patients. Women usually do not have a big win but use gambling as an escape from problems.
2. The progressive-loss phase, in which patients structure their lives around gambling and then move from being excellent gamblers to being stupid ones who take considerable risks, cash in securities, borrow money, miss work, and lose jobs.
3. The desperate phase, with patients frenziedly gambling with large amounts of money, not paying debts, becoming involved with loan sharks, writing bad checks, and possibly embezzling.
4. The hopeless stage of accepting that losses can never be made up, but the gambling continues because of the associated arousal or excitement. The disorder may take up to 15 yr to reach the last phase, but then, within a year or two, patients have totally deteriorated.

COURSE AND PROGNOSIS

Pathologic gambling usually begins in adolescence for men and late in life for women. The disorder waxes and wanes and tends to be chronic. Table 4-49 lists the four phases of pathologic gambling.

TREATMENT

Gamblers seldom come forward voluntarily to be treated. Legal difficulties, family pressures, or other psychiatric complaints bring gamblers to treatment. Gamblers Anonymous (GA) was founded in Los Angeles in 1957 and modeled on AA. It is accessible, at least in large cities, and is an effective treatment for gambling in some patients. GA is a method of inspirational group therapy that involves public confession, peer pressure, and the presence of reformed gamblers (as with sponsors in AA) available to help members resist the impulse to gamble. The dropout rate from GA is high, however. Hospitalization may sometimes help by removing patients from

their environments. Clinicians should not start insight-oriented psychotherapy until patients have been away from gambling for 3 months. At this point, patients who are pathologic gamblers may become excellent candidates for this form of psychotherapy. Family therapy is often valuable. CBT (e.g., relaxation techniques combined with visualization of gambling avoidance) has had some success.

Psychopharmacological treatment, once largely unsuccessful, now plays a significant role in the management of pathologic gamblers. Useful agents include antidepressants, notably SSRIs and bupropion; mood stabilizers, including sustained-release lithium and antiepileptics such as lamotrigine; atypical antipsychotics; and opioid agents such as naltrexone. In many patients, it is difficult to determine whether an antidepressant or mood stabilizer alleviates gambling cravings directly or via treatment of a comorbid condition, particularly depressive or bipolar disorders.

EPIDEMIOLOGY

Although we lack comprehensive worldwide statistics, available information indicates that 1 to 2 percent of the general population are problem gamblers. Problem gambling is more common in men and young adults than in women and older adults; however, escalation has been noted in the poor, notably poor minorities, adolescents, elderly retirees, and women. Pathologic gambling is associated with intimate partner violence—both as a perpetrator (for both men and women) and as a victim (typically women only). However, this violence is also due to comorbid psychiatric and substance use disorders.

ETIOLOGY

Psychosocial Factors

Several factors have been described as predisposing persons to develop the disorder: loss of a parent by death, separation, divorce, or desertion before a child is 15 years of age; inappropriate parental discipline (absence, inconsistency, or harshness); exposure to, and availability of, gambling activities for adolescents; a family emphasis on material and financial symbols; and a lack of family emphasis on saving, planning, and budgeting.

Psychoanalytic theory has focused on several core character difficulties.

Edmund Bergler suggested that compulsive gamblers have an unconscious desire to lose and gamble to relieve unconscious feelings of guilt, though these ideas are questionable. Another suggestion is that the gamblers are narcissists whose grandiose and omnipotent fantasies lead them to believe they can control events and even predict their outcome. Learning theorists view uncontrolled gambling as resulting from erroneous perceptions about control of impulses.

Biologic Factors

Many studies indicate that pathologic gamblers suffer from complex neurotransmitter dysregulation, similar to the abnormalities found in substance use disorders and patients with other behavioral/impulsive problems. Most major neurotransmitters have, at some point, been implicated as a significant factor in the dysfunction of cerebral sites and pathways mediating behavioral arousal, inhibition/disinhibition, reward/reinforcement, and psychophysiological stress.

The particular focus on the role of increased dopaminergic activity in pathologic gambling arose from the serendipitous discovery that approximately one-third of patients receiving dopamine agonists for Parkinson disease develop the illness without any previous history. The gambling excesses of these patients usually disappear upon withdrawal of the offending drug.

▲ 4.13 Other Disorders Related to the Addictive Disorders

INTERNET GAMING DISORDER

Also called *Internet Addiction,* such persons spend almost all their waking hours at their computer. Their patterns of use are repetitive and constant, and they are unable to resist intense urges to use the computer or to "surf" the internet. Internet addicts may gravitate to certain sites that meet specific needs (e.g., shopping, sex, and interactive games, among others). In DSM-5, there is a condition proposed for further study called "internet gaming

disorder," which refers to persons who continually use the internet to play games to the extent that it interferes with social relations and work performance. However, as mentioned earlier, the disorder need not be limited to games. Other activities may be involved. General population surveys show a wide range of reported prevalence, from 0 to almost 50 percent, with some of the highest percentages reported in South Asian countries.

Table 4-50
Symptoms of Internet Gaming Disorder

Activities associated with Gaming
Preoccupation w/ gaming
Withdrawal (discomfort when deprived of gaming)
Tolerance (spending more time to achieve same enjoyment from the game)

Compulsive Behavior
Lack of control around gaming

Social or Occupational Dysfunction
Decreased alternative activities
Negative effects on personal relationships, occupational or school performance due to gaming
Lying to loved ones or clinicians about the frequency of gaming
Relying on gaming to improve mood
Continued use despite recognize the harmful effects of compulsive gaming

Table 4-50 lists some of the common symptoms and effects of the disorder. They are organized so as to be consistent with the DSM-5 approach to substance use disorder (see Section 4.1).

Internet Use and Victims

The combination of anonymity, convenience, and escape (the ACE model) promotes the internet as a focus of psychopathology. It can be easy to conceal one's identity and even create alternate identities using various internet platforms. The resulting deception can take a malignant turn as sexual

predators deceive their victims with false identities only to exploit and harm them when they meet. These contacts are unregulated and difficult to detect except by monitoring and checking the computers used. There are frequent reports of minors having been lured into sometimes lethal situations by sexual predators. Occasionally there is a report of a couple that met to marry only to discover they had missed verifying crucial details, such as each other's sex.

Some people who make little use of the internet nonetheless become victims and enter treatment. The suicide of one teenager after reading untruths entered by a peer's malicious mother ("cyberbullying") has inspired laws to criminalize such behavior. Internet identity theft is also rampant. An underreported and growing problem, medical identity theft, is harder to detect and remedy, often requiring painstaking record correction.

MOBILE OR CELL PHONE COMPULSION

Some persons compulsively use mobile or smartphones. Often these individuals find themselves engaging in many of the same patterns of behavior as those with the proposed internet gaming disorder, though the focus is not specifically on the internet or gaming. These individuals may be preoccupied with checking for new messages (text or email), new social media posts, or other smartphone-related activities.

REPETITIVE SELF-MUTILATION

Persons who repeatedly cut themselves or do damage to their bodies may do so in a compulsive manner. Parasuicidal behavior is typical in, but not limited to, borderline personality disorder. Compulsive body piercing or tattooing may be a symptom of a paraphilia or a depressive equivalent.

In DSM-5, there is a proposed diagnosis called "non-suicidal self-injury" to refer to persons who repeatedly damage their bodies, who, however, do not wish to die, contrasted with those persons who harm themselves with real suicidal intent. Most individuals who engage in this behavior do so to obtain relief from dysphoric states or to resolve a conflict. Cutting the skin or inflicting bodily pain may release endorphins or raise dopamine levels in the brain, both of which contribute to a euthymic or elated mood, thus alleviating

depressed states of mind in those who practice self-mutilation.

COMPULSIVE SEXUAL BEHAVIOR

Some persons repeatedly seek out sexual gratification, often in perverse ways (e.g., exhibitionism). They are unable to control their behavior and may not experience feelings of guilt after an episode of acting-out behavior. Sometimes called *sexual addiction,* we discuss this condition in the chapter on sexual disorders (Chapter 16).

Schizophrenia Spectrum and Other Psychotic Disorders

Although we tend to discuss schizophrenia as if it is a single disease, it likely comprises a group of disorders with heterogeneous etiologies, which includes patients whose clinical presentations, treatment response, and courses of illness vary. Signs and symptoms are variable and include changes in perception, emotion, cognition, thinking, and behavior. The expression of these symptoms varies across patients and over time, but the effect of the illness is always severe and is usually long-lasting. The disorder usually begins before age 25 years, persists throughout life, and affects persons of all social classes. Both patients and their families often suffer from inadequate care and social ostracism because of widespread ignorance about the disorder. Schizophrenia is one of the most common of the severe mental disorders, but its essential nature remains to be clarified. Thus, it is sometimes referred to as a syndrome, as a group of disorders, or, as in the fifth edition of the Diagnostic and Statistical Manual of Mental Disorders (DSM-5), the schizophrenia spectrum disorders. Clinicians should appreciate that the diagnosis of schizophrenia is based entirely on psychiatric history and mental status examination. There is no laboratory test for schizophrenia.

Because schizophrenia begins early in life, causes significant and long-lasting impairments, makes heavy demands for hospital care, and requires ongoing clinical care, rehabilitation, and support services, the financial cost of the illness in the United States likely exceeds that of all cancers combined. Patients with a diagnosis of schizophrenia account for 15 to 45 percent of homeless Americans, and about 5% of patients with schizophrenia per year are homeless. Worldwide, schizophrenia is one of the top 25 leading causes

of disability. This fact is striking, given its relatively low prevalence. However, this disorder affects not only individuals but families, caregivers, and societies overall. For this reason, indirect costs are enormous and often underestimated.

THE CLINICAL PRESENTATION

No clinical sign or symptom is pathognomonic for schizophrenia; every sign or symptom seen in schizophrenia occurs in other psychiatric and neurologic disorders. Therefore, a patient's history is essential for the diagnosis of schizophrenia; clinicians cannot diagnose schizophrenia only by results of a single mental status examination, as symptoms change with time. For example, a patient may have intermittent hallucinations and a varying ability to perform adequately in social situations, or significant symptoms of a mood disorder may come and go. The clinician should also take into account the patient's educational level, intellectual ability, and cultural and subcultural membership. An impaired ability to understand abstract concepts, for example, may reflect either the patient's education or intelligence. Religious organizations and cults may have customs that seem strange to outsiders but are typical to those within the cultural setting.

The appearance of a patient with schizophrenia can range from that of a completely disheveled, screaming, agitated person to an obsessively groomed, completely silent, and immobile person. Between these two extremes, patients may be talkative and may exhibit bizarre postures. Their behavior may become agitated or violent, apparently in an unprovoked manner, but usually in response to hallucinations. Patients with schizophrenia are often poorly groomed, fail to bathe, and dress too warmly for the prevailing temperatures. Other odd behaviors include tics, stereotypies, mannerisms, and, occasionally, echopraxia, in which patients imitate the posture or the behavior of the examiner.

Patient AB, a 32-year-old woman, began to lose weight and became careless about her work, which deteriorated in quality and quantity. She believed that other women at her place of employment were circulating slanderous stories concerning her and complained that a young man

employed in the same plant had put his arm around her and insulted her. Her family demanded that the charge be investigated, which showed not only that the charge was without foundation but also that the man in question had not spoken to her for months. One day she returned home from work, and as she entered the house, she laughed loudly, watched her sister-in-law suspiciously, refused to answer questions, and at the sight of her brother began to cry. She refused to go to the bathroom, saying that a man was looking in the windows at her. She ate no food, and the next day she declared that her sisters were "bad women," that everyone was talking about her, and that someone had been having sexual relations with her, and although she could not see him, he was "always around."

The patient was admitted to a public psychiatric hospital. As she entered the admitting office, she laughed loudly and repeatedly screamed in a loud tone, "She cannot stay here; she's got to go home!" She grimaced and performed various stereotyped movements of her hands. When seen on the ward an hour later, she paid no attention to questions, although she talked to herself in a childish tone. She moved about constantly, walked on her toes in a dancing manner, pointed aimlessly about, and put out her tongue and sucked her lips in the manner of an infant. At times she moaned and cried like a child but shed no tears. As the months passed, she remained silly, childish, preoccupied, and inaccessible, grimacing, gesturing, pointing at objects in a stereotyped way, and usually chattering to herself in a peculiar high-pitched voice, with little of what she said being understood. Her condition continued to deteriorate, she remained unkempt, and she presented a picture of extreme introversion and regression, with no interest either in the activities of the institution or in her relatives who visited her. (Adapted from case of Arthur P. Noyes, M.D., and Lawrence C. Kolb, M.D.)

Catatonic stupor, often referred to simply as catatonia, is a condition in which patients seem completely lifeless and may exhibit such signs as muteness, negativism, and automatic obedience. Waxy flexibility, once a common sign in catatonia, has become rare, as has manneristic behavior. A person with a less extreme subtype of catatonia may show marked social withdrawal and egocentricity, a lack of spontaneous speech or movement,

and an absence of goal-directed behavior. Patients with catatonia may sit immobile and speechless in their chairs, respond to questions with only short answers, and only move when directed. Other overt behavior may include odd clumsiness or stiffness in body movements.

Localizing and nonlocalizing neurologic signs (also known as hard and soft signs, respectively) are more common in patients with schizophrenia than in other psychiatric patients. Nonlocalizing signs include dysdiadochokinesia, astereognosis, primitive reflexes, and diminished dexterity. The presence of neurologic signs and symptoms correlates with increased severity of illness, affective blunting, and a poor prognosis. Other abnormal neurologic signs include tics, stereotypies, grimacing, impaired fine motor skills, abnormal motor tone, and abnormal movements. Most patients are not aware of their abnormal involuntary movements.

In addition to the disorder of smooth ocular pursuit (saccadic movement), patients with schizophrenia have an elevated blink rate. The elevated blink rate may reflect hyperdopaminergic activity.

The inability of schizophrenia patients to perceive the prosody of speech or to inflect their speech is characteristic of disorders of the nondominant parietal lobe. Other parietal lobe–like symptoms in schizophrenia include the inability to carry out tasks (i.e., apraxia), right–left disorientation, and a lack of concern about the disorder.

Mood

Two common affective symptoms in schizophrenia are reduced emotional responsiveness, sometimes severe enough to warrant the label of anhedonia, and overly active and inappropriate emotions such as extremes of rage, happiness, and anxiety. A flat or blunted affect can be a symptom of the illness itself, of the parkinsonian adverse effects of antipsychotic medications, or depression, and differentiating these symptoms can be a clinical challenge. Overly emotional patients may describe exultant feelings of omnipotence, religious ecstasy, terror at the disintegration of their souls, or paralyzing anxiety about the destruction of the universe. Other feeling tones include perplexity, a sense of isolation, overwhelming ambivalence, and depression.

Thoughts

Psychotic disorders are, first and foremost, thought disorders and the disorder may affect either the process or content of their thought or both. A schizophrenia patient's thoughts may be challenging to understand and elicit. However, this is essential, as thought symptoms may represent the core symptoms of schizophrenia.

Disorders of thought concern the way we formulate ideas and languages. We sometimes call these *formal thought disorders*. The examiner infers a disorder from what and how the patient speaks, writes, or draws. The examiner may also assess the patient's thought process by observing their behavior, especially in carrying out discrete tasks (e.g., in occupational therapy).

When mild, thought disorders might present as stilted or vague. As it worsens, associations become looser. The patient may display circumstantiality, tangential thinking, perseverative thinking, neologisms, echolalia, verbigeration, word salad, and mutism.

Delusions

Delusions, the most obvious example of a disorder of thought content, are varied in schizophrenia and may assume persecutory, grandiose, religious, or somatic forms.

Patients may believe that an outside entity controls their thoughts or behavior or, conversely, that they extraordinarily control outside events (such as causing the sun to rise). Patients may have an intense and consuming preoccupation with esoteric, abstract, symbolic, psychological, or philosophic ideas. Patients may also worry about allegedly life-threatening but bizarre and implausible somatic conditions, such as the presence of aliens inside the patient's testicles affecting his ability to father children.

The phrase *loss of ego boundaries* describes the lack of a clear sense of where the patient's own body, mind, and influence end and where those of other animate and inanimate objects begin. For example, patients may think that other persons, the television, or the newspapers are referring to them (ideas of reference). Thought control, in which outside forces are controlling what the patient thinks or feels, is common, as is thought broadcasting, in which patients think others can read their minds or that they can broadcast

their thoughts through televisions.

Other signs of a loss of ego boundaries include the sense that the patient has physically fused with an external object (e.g., a tree or another person) or that the patient has disintegrated and fused with the entire universe (cosmic identity). With such a state of mind, some patients with schizophrenia doubt their gender or their sexual orientation. These symptoms should not be confused with gender identity problems.

Hallucinations

Any of the five senses may be affected by hallucinatory experiences in patients with schizophrenia. The most common hallucinations, however, are auditory, with voices that are often threatening, obscene, accusatory, or insulting. Two or more voices may converse among themselves, or a voice may comment on the patient's life or behavior.

A 48-year-old man, who had been diagnosed with schizophrenia while in the army at age 21 years, led an isolated and often frightened existence, living alone and supported by disability payments. Although he would confirm that he had chronic auditory hallucinations, he was never comfortable with discussing the content of these hallucinations, and a review of records showed this was a long-term pattern for the patient. Otherwise the patient had good rapport with his psychiatrist and was enthusiastic about the possibility of participating in a study of a novel antipsychotic agent. During the informed consent procedure, the patient asked about the possibility that the new medication might decrease his chronic auditory hallucinations. When it was acknowledged that any response was possible, including decreases in his hallucinations, the patient broke off the discussion abruptly and left the office. At a later visit, he reported that his most reliable pleasure in life was nightly discussions of gossip with hallucinations of voices he believed belonged to 17th-century French courtiers, and the chance that he might lose these conversations and the companionship they offered was too frightening for him to consider. (Adapted from Stephen Lewis, M.D., P. Rodrigo Escalona, M.D., and Samuel J. Keith, M.D.)

Visual hallucinations are common, but tactile, olfactory, and gustatory hallucinations are unusual; their presence should prompt the clinician to consider the possibility of an underlying medical or neurologic disorder that is causing the entire syndrome.

Psychotic disorders can affect other senses, as well. For example, *cenesthetic hallucinations* are unfounded sensations of altered states in bodily organs. Examples of cenesthetic hallucinations include a burning sensation in the brain, a pushing sensation in the blood vessels, and a cutting sensation in the bone marrow. Bodily distortions may also occur.

Cognition

Patients with schizophrenia are usually oriented to person, time, and place. The lack of such orientation should prompt clinicians to investigate the possibility of a medical or neurologic brain disorder. Some patients with schizophrenia may give incorrect or bizarre answers stemming from their delusions, such as "I am Christ; this is heaven, and it is AD 35."

Memory, as tested in the mental status examination, is usually intact, but there can be minor cognitive deficiencies. It may not be possible, however, to get the patient to attend closely enough to the memory tests for the ability to be assessed adequately.

A significant development in the understanding of the psychopathology of schizophrenia is the appreciation of subtle cognitive impairment. In outpatients, cognitive impairment is a better predictor of the level of function than is the severity of psychotic symptoms. Patients with schizophrenia typically exhibit subtle cognitive dysfunction in the domains of attention, executive function, working memory, and episodic memory. Although a substantial percentage of patients have average intelligence quotients, every person who has schizophrenia may have cognitive dysfunction compared with what he or she would be able to do without the disorder. Although these impairments cannot function as diagnostic tools, they are strongly related to the functional outcome of the illness and, for that reason, have clinical value as prognostic variables, as well as for treatment planning.

The cognitive impairment seems already to be present when patients have their first episode and appear largely to remain stable throughout the early illness. There may be a small subgroup of patients who have true dementia in

late life that is not due to other cognitive disorders, such as Alzheimer disease. Cognitive impairments are also present in attenuated forms in nonpsychotic relatives of schizophrenia patients.

The cognitive impairments of schizophrenia have become the target of pharmacologic and psychosocial treatment trials. Hopefully, effective treatments for these impairments will become available soon.

Insight and Judgment and Reliability

Classically, patients with schizophrenia have poor insight into the nature and severity of their disorder. The so-called lack of insight is associated with poor compliance with treatment. When examining schizophrenia patients, clinicians should carefully define various aspects of insight, such as awareness of symptoms, trouble getting along with people, and the reasons for these problems. Such information can be clinically useful in tailoring a treatment strategy and theoretically useful in postulating what areas of the brain contribute to the observed lack of insight (e.g., the parietal lobes).

A patient with schizophrenia is no less reliable than any other psychiatric patient. The nature of the disorder, however, requires the examiner to verify relevant information through additional sources.

Safety Concerns

Patients with schizophrenia may be agitated and have little impulse control when ill. They may also have decreased social sensitivity and appear to be impulsive when, for example, they grab another patient's cigarettes, change television channels abruptly, or throw food on the floor. Some impulsive behavior, including suicide and homicide attempts, may be in response to hallucinations commanding the patient to act.

Violent behavior (excluding homicide) is common among untreated schizophrenia patients, and the increased odds of a patient with schizophrenia committing acts of violence, compared to the general population, is 49% to 68%. Delusions of a persecutory nature, previous episodes of violence, and neurologic deficits are risk factors for violent or impulsive behavior. If a clinician feels fearful in the presence of a schizophrenic patient, they should take this as an internal clue that the patient may be on the verge of acting out violently. In such cases, the clinician should terminate the interview or

conduct it with an attendant at the ready.

Suicide. Suicide is the single leading cause of premature death among people with schizophrenia. The lifetime prevalence of suicidality in patients with schizophrenia is about 34.5 percent. Suicide attempts are made by 20 to 50 percent of the patients, with long-term rates of suicide estimated to be 10 to 13 percent. According to DSM-5, approximately 5 to 6 percent of schizophrenic patients die by suicide, but this is probably an underestimation. Often, suicide in schizophrenia seems to occur "out of the blue," without prior warnings or expressions of verbal intent. The most crucial factor is the presence of a major depressive episode. Epidemiologic studies indicate that up to 80 percent of schizophrenia patients may have a major depressive episode at some time in their lives. Some data suggest that those patients with the best prognosis (few negative symptoms, preservation of capacity to experience affects, better abstract thinking) can paradoxically also be at the highest risk for suicide. The profile of the patient at most significant risk is a young man who once had high expectations, declined from a higher level of functioning, realizes that his dreams are not likely to come true, and has lost faith in the effectiveness of treatment. Other possible contributors to the high rate of suicide include command hallucinations and drug abuse. Two-thirds or more of schizophrenic patients who commit suicide have seen an unsuspecting clinician within 72 hours of death. A large pharmacologic study suggests that clozapine may have particular efficacy in reducing suicidal ideation in schizophrenia patients with prior hospitalizations for suicidality. Adjunctive antidepressant medications may be effective for alleviating cooccurring major depression in schizophrenia.

Homicide. Despite the sensational attention that the news media provides when a patient with schizophrenia murders someone, the available data indicate that these patients are no more likely to commit homicide than is a member of the general population. When a patient with schizophrenia does commit homicide, it may be for unpredictable or bizarre reasons based on hallucinations or delusions. Possible predictors of homicidal activity are a history of previous violence, dangerous behavior while hospitalized, and hallucinations or delusions involving violence.

The Symptoms of Schizophrenia Can be Divided into Three Groupings

We can divide the symptoms of schizophrenia into three groups: positive, negative, and cognitive.

Positive Symptoms Are Abnormal Behaviors. Positive symptoms are symptoms that are present and usually observable. These are the symptoms associated with an acute psychotic episode and are primarily disorders of thought and presentation. They include hallucinations, delusions, and other bizarre behaviors. Table 5-1 lists examples of positive symptoms.

Negative Symptoms Are the Absence of Normal Behaviors. Negative symptoms are defined by their absence and sometimes also called deficit symptoms. They are commonly associated with the progression of the illness. These include the absence of affect, the absence of thought, the absence of motivation, the absence of pleasure, and the absence of attention. Table 5-2 lists examples of negative symptoms.

Cognitive Symptoms Are Impairments in Normal Cognitive Functions. The cognitive symptoms of schizophrenia may be subtle, particularly early in the disease process, but are very impairing and account for much of the disability associated with this disorder. They include impairments of attention, working memory, and executive functioning.

**Table 5-1
Positive Symptoms**

Hallucinations
    Auditory hallucinations
    Voices commenting
    Voices conversing
    Somatic or tactile hallucinations
    Olfactory hallucinations
    Visual hallucinations

Delusions

Persecutory delusions
Delusions of jealousy
Delusions of guilt or sin
Grandiose delusions
Religious delusions
Somatic delusions
Delusions of reference
Delusions of being controlled
Delusions of mind reading
Thought broadcasting
Thought insertion
Thought withdrawal

Bizarre behavior
Clothing and behavior
Social and sexual behavior
Aggressive behavior
Repetitive or stereotyped behavior

Positive formal thought disorder
Derailment
Tangentiality
Incoherence
Illogicality
Circumstantiality
Pressure of speech
Distractible speech
Clanging

Table 5-2
Negative Symptoms

Affective flattening or blunting
Unchanging facial expressions

Decreased spontaneous movement
Paucity of expressive gesture
Poor eye contact
Affective nonresponsivity
Inappropriate affect
Lack of vocal inflections

Alogia
Poverty of speech
Poverty of content of speech
Blocking
Increased latency of response

Avolition—apathy
Grooming and hygiene
Impersistence at work or school
Physical anergia

Anhedonia—asociality
Recreational interests and activities
Sexual interest and activities
Intimacy and closeness
Relationships with friends

Attention
Social inattentiveness
Inattentiveness during testing

Presentation in Special Populations

The Disorder in Children and Adolescents. A small minority of patients manifest schizophrenia in childhood. Such children may at first present diagnostic problems, particularly with differentiation from mental retardation and autistic disorder. Recent studies have established that we should base our diagnosis of childhood schizophrenia on the same symptoms used for adult schizophrenia. Its onset is usually insidious, its course tends to

be chronic, and the prognosis is mostly unfavorable.

The Disorder in Older People. Late-onset schizophrenia is clinically indistinguishable from schizophrenia but has an onset after age 45 years. This condition tends to appear more frequently in women and tends to be characterized by a predominance of paranoid symptoms. The prognosis is favorable, and these patients usually do well on antipsychotic medication.

DIAGNOSIS

Schizophrenia

Table 5-3 compares the different approaches to diagnosing schizophrenia. The patient should have evidence of a psychotic disorder. However, the presence of hallucinations or delusions is not necessary for a diagnosis of schizophrenia; the patient's disorder is diagnosed as schizophrenia when the patient demonstrates any two of the several symptoms included under the broad category of "psychotic symptoms." These symptoms should persist for an extended time: 6 months for DSM-5 and 1 month for ICD-10. The DSM-5 diagnostic criteria include course specifiers (i.e., prognosis) that offer clinicians several options and describe actual clinical situations.

Catatonic Type. The catatonic type of schizophrenia, which was prevalent several decades ago, has become rare in Europe and North America. The classic feature of the catatonic type is a marked disturbance in motor function; this disturbance may involve stupor, negativism, rigidity, excitement, or posturing.

Table 5-3
Schizophrenia

	DSM-5	ICD-10
Diagnostic name	Schizophrenia	Schizophrenia
Duration	Symptoms present continuously for at least 6 mo	

Symptoms	Delusions Hallucinations Disorganization of speech Disorganization of behavior or catatonia Negative symptoms	Thought distortions Perceptual disorders Negative affect, often blunted Possible cognitive dysfunction Other possible symptoms: • Thought echo • Thought insertion or withdrawal • Thought broadcasting • Delusional perception • Delusions of control, influence, or passivity • Hallucinatory voices • Disordered/disorganized thinking • Negative symptoms
Required number of symptoms	≥2, including at least 1 of the first 3 listed	Defined by the first three listed, although the other symptoms are considered common
Psychosocial consequences of symptoms	Functional impairment	
Exclusions (not better explained by):	Substances Other medical conditions Other psychiatric conditions	Other neurologic diseases Schizoaffective disorder Epilepsy Psychoactive substances
Symptom Specifiers	**With catatonia,** defined as presence of three or more	**Paranoid schizophrenia** —primarily defined by delusions. Less or no disturbance of affect or

| | of the following:
• ↓ psychomotor activity/stupor
• Catalepsy (holding a posture for an extended period)
• Waxy flexibility (hold a position but movable to a new posture as if made of wax)
• Mutism
• Negativism
• Posturing
• Odd mannerisms
• Stereotypic behaviors
• Agitation
• Grimacing
• Echolalia (imitating another's speech)
• Echopraxia (imitating another's movements) | volition
Hebephrenic schizophrenia —negative affect with inappropriate mood, social isolation and unpredictable behavior
Catatonic schizophrenia —psychomotor changes, such as posturing, odd mannerisms/affect, stupor vs. agitation
Undifferentiated Schizophrenia
Residual schizophrenia —chronic illness and cognitive changes resulting from a prolonged psychotic illness
Simple schizophrenia—slow progressive development of changes in behavior and functioning, affective blunting without preceding psychotic symptoms
Other Schizophrenia
Schizophrenia unspecified |
| Course specifiers | **First episode, currently in** | |

acute episode

First episode, currently in partial remission: currently less symptoms than needed for diagnosis

First episode, currently in full remission: 0 symptoms

Multiple episodes, currently in acute episode: ≥2 episodes

Multiple episodes, currently in partial remission

Multiple episodes, currently in full remission

Continuous

Unspecified

AC, age 32 years, was admitted to the hospital. On arrival, he was noted to be an asthenic, poorly nourished man with dilated pupils, hyperactive tendon reflexes, and a pulse rate of 120 beats/min. He showed many mannerisms, laid down on the floor, pulled at his foot, made undirected

violent striking movements, struck attendants, grimaced, assumed rigid and strange postures, refused to speak, and appeared to be having auditory hallucinations. When seen later in the day, he was found to be in a stuporous state. His face was without expression, he was mute and rigid, and he paid no attention to those about him or to their questions. His eyes were closed, and his eyelids could be separated only with effort. There was no response to pinpricks or other painful stimuli.

He gradually became accessible, and when asked concerning himself, he referred to his stuporous period as sleep and maintained that he had no recollection of any events occurring during it. He said, "I didn't know anything. Everything seemed to be dark as far as my mind is concerned. Then I began to see a little light, like the shape of a star. Then my head got through the star gradually. I saw more and more light until I saw everything in a perfect form a few days ago." He explained his mutism by saying that he had been afraid he would "say the wrong thing" and that he "didn't know exactly what to talk about." From his obviously inadequate emotional response and his statement that he was "a scientist and an inventor of the most extraordinary genius of the 20th century," it was plain that he was still far from well. (Adapted from case of Arthur P. Noyes, M.D., Lawrence C. Kolb, M.D.)

Sometimes the patient shows a rapid alternation between extremes of excitement and stupor. Associated features include stereotypies, mannerisms, and waxy flexibility. Mutism is particularly common. During catatonic excitement, patients need careful supervision to prevent them from hurting themselves or others. Patients also often require medical care because of malnutrition, exhaustion, hyperpyrexia, or self-inflicted injury.

Subtypes from Previous Versions of DSM. Previous versions of the DSM described subtypes of schizophrenia based predominantly on the clinical features. These were: paranoid, disorganized, catatonic, undifferentiated, and residual subtype. DSM-5 no longer includes these as experts in the field frequently questioned their validity. ICD-10 does continue to include them. Although having some face validity for clinicians, they have only a weak relationship to biologic variables, poor long-term stability, and

poor predictive value.

Schizoaffective Disorder

Schizoaffective disorder has features of both schizophrenia and mood disorders. In current diagnostic systems, patients can receive the diagnosis of schizoaffective disorder if they fit into one of the following six categories: (1) patients with schizophrenia who have mood symptoms, (2) patients with a mood disorder who have symptoms of schizophrenia, (3) patients with both mood disorder and schizophrenia, (4) patients with a third psychosis unrelated to schizophrenia and mood disorder, (5) patients whose disorder is on a continuum between schizophrenia and mood disorder, and (6) patients with some combination of the above. Clinicians frequently use a preliminary diagnosis of schizoaffective disorder when they are uncertain of the diagnosis.

It remains unclear whether the disorder is a subtype of schizophrenia, a mood disorder, or the simultaneous expression of each. It is unlikely that this represents a simultaneous expression of both disorders, as it appears to be more common than would be expected for coincidental co-occurrence. Schizoaffective disorder may also be a third distinct type of psychosis, one that is unrelated to either schizophrenia or a mood disorder. The most likely possibility is that schizoaffective disorder is a heterogeneous group of disorders encompassing all of these possibilities. As will be discussed below, the genetic abnormalities in schizophrenia overlap with that for mood disorders, making an overlap between the disorders more likely.

In the DSM-5 criteria for schizoaffective disorder, the clinician must accurately diagnose the mood disorder, making sure it meets the criteria of either a manic or depressive episode but also determining the exact length of each episode (not always easy or even possible). Table 5-4 compares the diagnostic approaches to schizoaffective disorder.

The length of each episode is critical for two reasons. First, to meet the requirement that the psychotic symptoms must also occur independently of the mood symptoms, it is essential to know when the affective episode ends, and the psychosis continues. Second, the relative lengths of the mood and psychotic episodes should be roughly equal, which requires us to know the course of the episodes.

Mrs. P is a 47-year-old, divorced, unemployed woman who lived alone and who experienced chronic psychotic symptoms despite treatment with olanzapine 20 mg per day and citalopram 20 mg per day. She believed that she was getting messages from God and the police department to go on a mission to fight against drugs. She also believed that an organized crime group was trying to stop her in this pursuit. The onset of her illness began at age 20 years when she experienced the first of several depressive episodes. She also described periods when she felt more energetic and talkative, had a decreased need for sleep, and was more active, sometimes cleaning her house throughout the night. About 4 years after the onset of her symptoms, she began to hear "voices" that became stronger when she was depressed but were still present and disturbed her even when her mood was euthymic. About 10 years after her illness began, she developed the belief that policemen were everywhere and that the neighbors were spying on her. She was hospitalized voluntarily. Two years later, she had another depressive episode, and the auditory hallucinations told her she could not live in her apartment. She was tried on lithium, antidepressants, and antipsychotic medications but continued to be chronically symptomatic with mood symptoms as well as psychosis.

Mrs. P demonstrates a "classic" presentation of schizoaffective disorder in which clear depressive and hypomanic episodes are present in combination with continuous psychotic illness and first-rank symptoms. Her course is typical of many individuals with schizoaffective disorder.

Schizophreniform Disorder

The symptoms of schizophreniform are similar to those of schizophrenia. However, with schizophreniform disorder, the symptoms are short term, lasting at least 1 month but less than 6 months. Patients with schizophreniform disorder should then return to their baseline level of functioning.

Like schizoaffective disorder, schizophreniform disorder appears to be a heterogeneous disorder. Many patients seem to have a disorder that is similar to schizophrenia, while others may have a disorder more like a mood disorder.

Table 5-5 compares the diagnostic approaches to schizophreniform disorder.

The disorder is an acute psychotic disorder with a rapid onset. It lacks a long prodromal phase. Although many patients with schizophreniform disorder may experience functional impairment at the time of an episode, they are unlikely to report a progressive decline in social and occupational functioning. The initial symptom profile is the same as for schizophrenia in that two or more psychotic symptoms must be present.

By definition, patients with schizophreniform disorder have the symptoms for at least a month and return to their baseline state within 6 months. In some instances, the illness is episodic, with more than one episode occurring after long periods of full remission. If the combined duration of symptomatology exceeds 6 months, however, then schizophrenia should be considered.

Mr. C, a 28-year-old accountant, was brought to the emergency department by the police in handcuffs. He was disheveled and shouted and struggled with the police officers. It was apparent that he was hearing voices because he would respond to them with shouts such as, "Shut up! I told you I won't do it!" However, when confronted about the voices, he denied hearing anything. Mr. C had a hypervigilant stare and jumped at the slightest noise. He stated that he must run away quickly because he knew he would be killed shortly otherwise.

Mr. C was functioning well until 2 months before hospitalization. He was an accountant at a prestigious company and had close friends and a live-in girlfriend. Most people who knew him would describe him as friendly, but he was occasionally quarrelsome.

When his girlfriend suddenly broke off the relationship and moved out of their apartment, Mr. C was distressed. However, he was convinced that he could win her back, so he began to "accidentally" run into her at her job or her new apartment with flowers and various gifts. When she strongly told him that she wanted nothing more to do with him and requested that he leave her alone, Mr. C was convinced that she wanted him dead. He became so preoccupied with this notion that his work began to suffer. Out of fear for his life, Mr. C took off from work frequently,

and when he did report to work, he was often tardy and did subpar work, making many errors. His supervisor confronted Mr. C about his behavior, threatening termination if it continued. Mr. C was embarrassed and resented his supervisor for the confrontation. He believed that his ex-girlfriend had hired the supervisor to kill him.

His beliefs were confirmed by a voice that would mock him. The voice told him time and again that he should quit his job, relocate to another city, and forget about his ex-girlfriend, but Mr. C refused, believing it would give them "more satisfaction than they deserved." He continued working, albeit cautiously, all the while fearing for his life.

Through it all, Mr. C believed himself to be the lone victim. He would awake abruptly at night from nightmares but would be able to fall right back to sleep. He had not lost any weight and had no other vegetative symptoms. His affect alternated between rage and terror. His mind was unusually alert and active, but he was not otherwise hyperactive, excessively energetic, or expansive. He did not display any formal thought disorder.

Mr. C was hospitalized and treated with antipsychotic medication. His symptoms remitted after several weeks of treatment, and he was well and able to return to work shortly after discharge.

Table 5-4
Schizoaffective Disorder

**Table 5-5
Schizophreniform Disorder**

	DSM-5	ICD-10
Diagnostic name	Schizophreniform Disorder	Acute and Transient psychotic disorder
Duration	≥1 mo, but <6 mo	<1 mo on average
Symptoms	Same as schizophrenia (see Table 5-3)	Symptoms of schizophrenia, including: Thought echo Thought insertion or withdrawal Thought broadcasting Delusional perception Delusions of control, influence, or passivity

		Hallucinatory voices Disordered/disorganized thinking Negative symptoms May or may not be associated with polymorphic (unstable, frequently changing) delusions, hallucinations and/or behavioral symptoms
Required number of symptoms	Same as schizophrenia (see Table 5-3)	
Exclusions (not better explained by):	Same as schizophrenia (see Table 5-3)	If symptoms persist, diagnosis should be changed to schizophrenia
Symptom Specifiers	**With catatonia:** See Table 5-3 for catatonia symptoms	
Course specifiers	**With good prognostic features:** ≥2 of following: Psychotic symptoms within 4 wk of initial behavioral changes Confusion Good premorbid function No negative	

Perhaps 60 to 80 percent of patients with this disorder will later develop schizophrenia. The remaining may have relapses of similar time-limited episodes of the disease, whereas some, although unfortunately only a few patients, will have only a single episode.

Brief Psychotic Disorder

Brief psychotic disorder is defined as a psychotic condition that involves the sudden onset of psychotic symptoms, which lasts 1 day or more but less than 1 month. Remission is full, and the individual returns to the premorbid level of functioning. Brief psychotic disorder is an acute and transient psychotic syndrome. The exact incidence and prevalence of brief psychotic disorder is not known, but it is generally considered uncommon. The disorder occurs more often among younger patients (20s and 30s) than among older patients. Brief psychotic disorder is more common in women than in men. Such epidemiologic patterns are sharply distinct from those of schizophrenia. Some clinicians indicate that the disorder may be seen most frequently in patients from low socioeconomic classes and in those who have experienced disasters or major cultural changes (e.g., immigrants). The age of onset in industrialized settings may be higher than in developing countries. Table 5-6 compares the diagnostic approaches to brief psychotic disorder.

The cause of the disorder is not known, however it is common in patients with personality disorders. Persons who have gone through major psychosocial stressors may be at greater risk for subsequent brief psychotic disorder.

The symptoms of brief psychotic disorder always include at least one major symptom of psychosis, such as hallucinations, delusions, and disorganized thoughts, usually with an abrupt onset, but do not always include the entire symptom pattern seen in schizophrenia. Some clinicians have observed that labile mood, confusion, and impaired attention may be more common at the onset of brief psychotic disorder than at the onset of

eventually chronic psychotic disorders. Characteristic symptoms in brief psychotic disorder include emotional volatility, strange or bizarre behavior, screaming or muteness, and impaired memory of recent events. Some of the symptoms suggest a diagnosis of delirium and warrant a medical workup, especially to rule out adverse reactions to drugs.

Table 5-6
Brief Psychotic Disorder

	DSM-5	ICD-10
Diagnostic name	Brief Psychotic Disorder	See Table 5-5 definition of Acute and Transient psychotic disorder—ICD 10 does not distinguish between these two disorders
Duration	≥1 day, <1 mo with return to baseline	
Symptoms	Same as for schizophrenia (see Table 5-3) except negative symptoms not included	
Required number of symptoms	1 of first 3 symptoms (delusions, hallucinations or disorganized speech) +/- behavioral symptoms	
Exclusions (not better explained	Culturally sanctioned response/behavior Another mental illness	

by):	Substance use Another medical condition

Course specifiers	**With peripartum onset:** during pregnancy or ≤4 wk after delivery

A 20-year-old man was admitted to the psychiatric ward of a hospital shortly after starting military duty. During the first week after his arrival to the military base, he thought the other recruits looked at him in a strange way. He watched the people around him to see whether they were out "to get" him. He heard voices calling his name several times. He became increasingly suspicious and after another week had to be admitted for psychiatric evaluation. There he was guarded, scowling, skeptical, and depressed. He gave the impression of being very shy and inhibited. His psychotic symptoms disappeared rapidly when he was treated with an antipsychotic drug. However, he had difficulties in adjusting to hospital life. Transfer to a long-term medical hospital was considered, but after 3 months, a decision was made to discharge him to his home. He was subsequently judged unfit to return to military services.

The patient was the eldest of five siblings. His father was an intemperate drinker who became angry and brutal when drunk. The family was poor, and there were constant fights between the parents. As a child, the patient was inhibited and fearful and often ran into the woods

when troubled. He had academic difficulties.

When the patient got older, he preferred to spend time alone and disliked being with people. He occasionally took part in local parties. Although he was never a heavy drinker, he often got into fights when he had a drink or two.

The patient was reinterviewed by hospital personnel at 4 years, 7 years, and 23 years after his admission. He has had no recurrences of any psychotic symptoms and has been fully employed since 6 months after he left the hospital. He married, and at the last follow-up, he had two grown children.

After leaving the hospital, the patient worked for 2 years in a factory. For the past 20 years, he has managed a small business, and it has run well. He has been very happy at work and in his family life. He has made an effort to overcome his tendency toward isolation and has several friends.

The patient believes that his natural tendency is to be socially isolated and that his disorder was connected with the fact that in the military, he was forced to deal with other people. (Adapted from Laura J. Fochtmann, M.D., Ramin Mojtabai, M.D., Ph.D., M.P.H., and Evelyn J. Bromet, Ph.D.)

Delusional Disorder

The diagnosis of delusional disorder is made when a person exhibits one or more delusions of at least 1 month's duration that cannot be attributed to other psychiatric disorders. The delusions are often nonbizarre, meaning that the delusions are about situations that can occur in real life, such as being followed, infected, loved at a distance, and so on; that is, they usually have to do with phenomena that, although not real, are nonetheless possible. Several types of delusions may be present. Table 5-7 compares the diagnostic approaches to delusional disorder.

Table 5-7
Delusional Disorder

DSM-5	ICD-10

Diagnostic name	Delusional Disorder	Delusional Disorder
Duration	≥1 mo	
Symptoms	Delusions (see symptom specifiers for examples)	Delusions Persistent +/- hallucinations
Required number of symptoms	≥1	≥1 delusions
Psychosocial consequences of symptoms	No marked functional impairment	
Exclusions (not better explained by):	Schizophrenia Another medical condition Substance use Another mental illness	Personality disorder Psychosis Psychogenic reaction Schizophrenia
Symptom Specifiers	**Erotomanic type** **Grandiose type** **Jealous type** **Persecutory type** **Somatic type** **Mixed type** **Unspecified type** **With bizarre content:** if not related to reality or a life experience or not possible, include this specifier	
Course specifiers	**First episode, currently in acute episode**	

First episode, currently in partial remission: currently less symptoms than needed for diagnosis

First episode, currently in full remission: 0 symptoms

Multiple episodes, currently in acute episode: ≥2 episodes

Multiple episodes, currently in partial remission

Multiple episodes, currently in full remission

Continuous

Unspecified

Patients are usually well groomed and well dressed, without evidence of gross disintegration of personality or of daily activities, yet they may seem eccentric, odd, suspicious, or hostile. They are sometimes litigious and may make this inclination clear to the examiner. The most remarkable feature of patients with delusional disorder is that the mental status examination shows them to be quite normal except for a markedly abnormal delusional system. Patients may attempt to engage clinicians as allies in their delusions, but a clinician should not pretend to accept the delusion; this collusion further confounds reality and sets the stage for eventual distrust between the patient and the therapist.

Patients' moods are consistent with the content of their delusions. A patient with grandiose delusions is euphoric; one with persecutory delusions is suspicious. Whatever the nature of the delusional system, the examiner may sense some mild depressive qualities.

By definition, patients with delusional disorder do not have prominent or sustained hallucinations. A few delusional patients have other hallucinatory experiences—virtually always auditory rather than visual. They also have generally normal cognition apart from their delusion.

The disorders can be of several types, and in the diagnosis the clinician

should specify the type. The types include: persecutory (believing others are trying to harm them), jealous (believing that a lover or partner is unfaithful), erotomanic (believing that another person, often of higher status, is in love with them), somatic (believing the person has some physical disorder), and grandiose (a "delusion of grandeur"). There is also a mixed and unspecified type, for delusions that are a combination of types or not described by one of the categories. Of these types, persecutory and jealous are probably the most common.

Mrs. S, a 62-year-old-woman, was referred to a psychiatrist because of reports of being unable to sleep. She had previously worked full time taking care of children, and she played tennis almost every day and managed her household chores. However, she had now become preoccupied with the idea that her downstairs neighbor was doing a variety of things to harass her and wanted to get her to move away. At first, Mrs. S based her belief on certain looks that he gave her and damage done to her mailbox, but later she felt he might be leaving empty bottles of cleaning solutions in the basement so she would be overcome by fumes. As a result, the patient was fearful of falling asleep, convinced that she might be asphyxiated and unable to awaken in time to get help. She felt somewhat depressed and thought her appetite might be decreased from the stress of being harassed. However, she had not lost weight and still enjoyed playing tennis and going out with friends. At one point she considered moving to another apartment but then decided to fight back. The episode had gone on for 8 months when her daughter persuaded her to have a psychiatric assessment. In the interview, Mrs. S was pleasant and cooperative. Except for mild depressive symptoms and the specific delusion about being harassed by her neighbor, her mental status was normal.

Mrs. S had a past history of depression 30 years before, which followed the death of a close friend. She saw a counselor for several months and found this helpful, but she was not treated with medication. For the current episode, she agreed to take medications, although she believed her neighbor was more in need of treatment than she was. Her symptoms improved somewhat with risperidone 2 mg at bedtime and

clonazepam 0.5 mg every morning and at bedtime.

This patient presented with a single delusion regarding her neighbor that was within the realm of possibility (i.e., not bizarre). Other areas of her functioning were normal. Although mild depressive symptoms were present, she did not meet criteria for major depressive disorder. Her prior symptoms of depression appeared to be related to a normal bereavement reaction and had not required pharmacotherapy or hospitalization. Thus, her current presentation is one of delusional disorder, persecutory type and not major depressive disorder with psychotic features. In terms of treatment, the ability to create a working alliance with the patient, avoiding the discussion of the veracity of her delusion, and focusing on her anxiety, depression, and difficulty falling asleep enabled her psychiatrist to introduce the medications with beneficial results. (Courtesy of Laura J. Fochtmann, M.D., Ramin Mojtabai, M.D., Ph.D., M.P.H., and Evelyn J. Bromet, Ph.D.)

Mr. M was a 51-year-old married white man who lived with his wife in their own home and who worked full time driving a sanitation truck. Before his hospitalization, he became concerned that his wife was having an affair. He began to follow her, kept notes on his observations, and badgered her constantly about this, often waking her up in the middle of the night to make accusations. Shortly before admission, these arguments led to physical violence, and he was brought to the hospital by police. In addition to concerns about his wife's fidelity, Mr. M reported feelings of depression over his wife's "betrayal of [their] marriage vows," but he noted no changes in sleep, appetite, or work-related functioning. He was treated with a low dose of an antipsychotic medication and described being less concerned about his wife's behavior. After discharge, he remained on medications and was seen by a psychiatrist monthly, but 10 years later, he continued to believe that his wife was unfaithful. His wife noted that he sometimes became upset about the delusion but that he had not become aggressive or required readmission.

This patient experienced a fixed, encapsulated delusion of jealousy that did not interfere with his other activities and that showed a partial

response to antipsychotic medications. Although he initially reported feeling somewhat depressed over his wife's perceived infidelity, he did not have other symptoms suggestive of a major depressive episode. (Courtesy of Laura J. Fochtmann, M.D., Ramin Mojtabai, M.D., Ph.D., M.P.H., and Evelyn J. Bromet, Ph.D.)

Little is known about the epidemiology of delusional disorder as it is rare, and is, likely, a heterogeneous group of disorders that manifest as delusions. Despite many theories, the causes are not known. Many patients with the disorder can function well in society and never come to psychiatric attention. Psychiatrists may only meet them when they are evaluating them for another disorder, such as major depressive disorder. Other times, a physician may request a psychiatric consult for a patient they are evaluating for some other medical disorder and notice some odd responses. The disorder appears to be stable over time. Although reliable data are limited, patients with persecutory, somatic, and erotomanic delusions are thought to have a better prognosis than patients with grandiose and jealous delusions.

Other Psychotic Disorders

Patients may present with psychotic symptoms that are not easily described by one of the psychotic disorders. Some examples include patients with persistent auditory hallucination but no other symptoms, or delusions that present with significant mood symptoms. In some cases a clinician may consider the symptoms that seem psychotic to be so minor as not to deserve a diagnosis of a typical disorder; these can include very transient symptoms or presentations where the patient seems to have full insight into their delusions or hallucinations.

One pattern of psychosis that deserves mention is the presence of delusional symptoms in a partner of an individual with delusional disorder, commonly called "shared psychosis," or *folie á deux*. It is probably rare, but incidence and prevalence figures are lacking, and the literature consists almost entirely of case reports.

The disorder is characterized by the transfer of delusions from one person to another. Both persons are closely associated for a long time and typically live together in relative social isolation. In its most common form (and the

one recognized in DSM-5), the individual who first has the delusion (the primary case) is often chronically ill and typically is the influential member of a close relationship with a more suggestible person (the secondary case) who also develops the delusion. The person in the secondary case is frequently less intelligent, more gullible, more passive, or more lacking in self-esteem than the person in the primary case. If the pair separates, the secondary person may abandon the delusion, but this outcome is not seen uniformly. The occurrence of the delusion is attributed to the strong influence of the more dominant member. Old age, low intelligence, sensory impairment, cerebrovascular disease, and alcohol abuse are among the factors associated with this peculiar form of psychotic disorder. A genetic predisposition to idiopathic psychoses has also been suggested as a possible risk factor.

Other special forms have been reported, such as *folie simultanée*, in which two persons become psychotic simultaneously and share the same delusion. Occasionally, more than two individuals are involved (e.g., *folie á trois, quatre, cinq*; also *folie á famille*), but such cases are especially rare. The most common relationships in shared psychotic disorder are sister–sister, husband–wife, and mother–child, but other combinations have also been described. Almost all cases involve members of a single family.

A 52-year-old man was referred by the court for inpatient psychiatric examination, charged with disturbing the peace. He had been arrested for disrupting a trial, complaining of harassment by various judges. He had walked into a courtroom, marched to the bench, and begun to berate the probate judge. While in the hospital, he related a detailed account of conspiratorial goings-on in the local judiciary. A target of certain judges, he claimed he had been singled out for a variety of reasons for many years: he knew what was going on; he had kept records of wrongdoings; and he understood the significance of the whole matter. He refused to elaborate on the specific nature of the conspiracy. He had responded to it with frequent letters to newspapers, the local bar association, and even to a Congressional subcommittee. His mental state, apart from his story and a mildly depressed mood, was entirely normal.

A family interview revealed that his wife and several grown children

shared the belief in a judicial conspiracy directed against the patient. There was no change in delusional thinking in the patient or the family after 10 days of observation. The patient refused follow-up.

In this case, protection is provided by others who share the delusion and believe in the reasonableness of the response; such cases are uncommon, if not rare. (Courtesy of TC Manschreck, M.D.)

OBJECTIVE TESTS FOR THE DISORDER

Schizophrenia and the other psychotic disorders remain clinical diagnoses and no tests are sensitive or specific enough for diagnostic purposes. Most tests, such as serologic testing, are mainly used to rule out other causes of psychosis (such as syphilis or anti-NMDA receptor encephalitis). However, some tests are abnormal on average when comparing groups of patients with schizophrenia to patients without the disorder. Examples include computerized electroencephalogram (EEG), which show differences in event-related potentials.

Diagnostic and Rating Scales for Schizophrenia

Several diagnostic interviews and rating scales exist for schizophrenia. Some are useful for diagnosing the disorder, although they are mainly used in research settings.

Most scales measure the outcomes of various interventions, not the presence of a diagnosis. They focus on measuring clinical symptoms associated with the disorder. These include the Positive and Negative Syndrome Scale (PANSS), and the Brief Psychiatric Rating Scale (BPRS), both of which can track the significant symptoms of the disorder. We can assess for extrapyramidal symptoms with a variety of instruments, but the Simpson Angus Scale (SAS), the Abnormal Involuntary Movement Scale (AIMS) and Barnes Akathisia Rating Scale (BARS) are most common.

Psychological Testing

Patients with schizophrenia generally perform poorly on a wide range of neuropsychological tests. Vigilance, memory, and concept formation are most affected and consistent with pathologic involvement in the

frontotemporal cortex.

Objective measures of neuropsychological performance, such as the Halstead–Reitan battery and the Luria–Nebraska battery, often give abnormal findings, such as bilateral frontal and temporal lobe dysfunction, including impairments in attention, retention time, and problem-solving ability. Motor ability is also impaired, possibly related to brain asymmetry.

Intelligence Tests. When comparing groups of patients with schizophrenia with groups of psychiatric patients without schizophrenia or from the general population, schizophrenia patients tend to score lower on intelligence tests. Statistically, the evidence suggests that low intelligence is often present at the onset, and intelligence may continue to deteriorate with the progression of the disorder.

Projective and Personality Tests. Projective tests, such as the Rorschach test and the Thematic Apperception Test, may indicate bizarre ideation. Personality inventories, such as the Minnesota Multiphasic Personality Inventory, often give abnormal results in schizophrenia, but the contribution to diagnosis and treatment planning is minimal.

DIFFERENTIAL DIAGNOSIS FOR PSYCHOTIC DISORDERS

Secondary Psychotic Disorders

A wide range of nonpsychiatric medical conditions and a variety of substances can induce symptoms of psychosis and catatonia (Table 5-8). The most appropriate diagnosis for such symptoms is a psychotic disorder due to a general medical condition, catatonic disorder due to a general medical condition, or substance-induced psychotic disorder.

When evaluating a patient with psychotic symptoms, clinicians should follow the general guidelines for assessing nonpsychiatric conditions. First, clinicians should aggressively pursue an undiagnosed nonpsychiatric medical condition when a patient exhibits any unusual or rare symptoms or any variation in the level of consciousness. Second, clinicians should attempt to obtain a complete family history, including a history of medical, neurologic,

and psychiatric disorders. Third, clinicians should consider the possibility of a nonpsychiatric medical condition, even in patients with previous diagnoses of schizophrenia. A patient with schizophrenia is just as likely to have a brain tumor that produces psychotic symptoms, as is a patient without schizophrenia.

Table 5-8
Potential Medical Etiologies of Delusional Syndromes

Disease or Disorder Class	Examples
Neurodegenerative disorders	Alzheimer disease, Pick disease, Huntington disease, basal ganglia calcification, multiple sclerosis, metachromatic leukodystrophy
Other central nervous system disorders	Brain tumors, especially temporal lobe and deep hemispheric tumors; epilepsy, especially complex partial seizure disorder; head trauma (subdural hematoma); anoxic brain injury; fat embolism
Vascular disease	Atherosclerotic vascular disease, especially when associated with diffuse, temporoparietal, or subcortical lesions; hypertensive encephalopathy; subarachnoid hemorrhage, temporal arteritis
Infectious disease	HIIV/AIDS encephalitis lethargica, Creutzfeldt–Jakob disease, syphilis, malaria, acute viral encephalitis
Metabolic disorder	Hypercalcemia, hyponatremia, hypoglycemia, uremia, hepatic encephalopathy, porphyria
Endocrinopathies	Addison disease, Cushing syndrome, hyper-

	or hypothyroidism, panhypopituitarism
Vitamin deficiencies	Vitamin B_{12} deficiency, folate deficiency, thiamine deficiency, niacin deficiency
Medications	Adrenocorticotropic hormones, anabolic steroids, corticosteroids, cimetidine, antibiotics (cephalosporins, penicillin), disulfiram, anticholinergic agents
Substances	Amphetamines, cocaine, alcohol, cannabis, hallucinogens
Toxins	Mercury, arsenic, manganese, thallium

Mood Disorders

A patient with a major depressive episode may present with delusions and hallucinations, as can a patient with bipolar disorder. Delusions seen with psychotic depression are typically mood-congruent and involve themes such as guilt, self-depreciation, deserved punishment, and incurable illnesses. In mood disorders, psychotic symptoms resolve entirely with the resolution of depression. A depressive episode that is this severe may also result in loss of functioning, a decline in self-care, and social isolation, but these are secondary to the depressive symptoms and should not be confused with the negative symptoms of schizophrenia.

A full-blown manic episode often presents with delusions and sometimes hallucinations. Delusions in mania are most often mood-congruent and typically involve grandiose themes. The flight of ideas seen in mania may, at times, be confused with the thought disorder of schizophrenia. Special attention during the mental status examination of a patient with a flight of ideas is required to note whether the associative links between topics are conserved. However, the conversation is awkward for the observer to follow because of the patient's accelerated rate of thinking.

Personality Disorders

Various personality disorders may have some features of schizophrenia. Schizotypal, schizoid, and borderline personality disorders are personality

disorders with several overlapping symptoms. A severe obsessive-compulsive personality disorder may mask an underlying schizophrenic process. Personality disorders, unlike schizophrenia, have mild symptoms and a history of occurring throughout a patient's life; they also lack an identifiable date of onset.

Malingering and Factitious Disorders

For a patient who imitates the symptoms of schizophrenia but does not have the disorder, either malingering or factitious disorder may be an appropriate diagnosis. Although truly mimicking the symptoms of schizophrenia is difficult, especially in front of an experienced clinician, persons have faked schizophrenic symptoms and have been admitted into and treated at psychiatric hospitals. The condition of patients who are entirely in control of their symptom production may qualify for a diagnosis of malingering; such patients usually have some apparent financial or legal reason to want to be considered mentally ill. The condition of patients who are less in control of their falsification of psychotic symptoms may qualify for a diagnosis of factitious disorder. Some patients with schizophrenia, however, may falsely complain of an exacerbation of psychotic symptoms to obtain increased assistance benefits or to gain admission to a hospital.

COMORBIDITY

Substance Use Disorders

Comorbid substance use disorders in patients with schizophrenia are widespread, with a lifetime prevalence of 74%. Tobacco, alcohol, cannabis, and cocaine use disorders are most common, and almost half of the patients with schizophrenia will have a severe problem with drugs or alcohol during their lifetime.

The link between the two disorders is not clear, and experts in the field have proposed several explanations. The diathesis-stress model suggests that a biologically vulnerable person, when encountering external stress (of which a substance may be one), is more likely to develop schizophrenia. The self-medication hypothesis suggests that patients use substances to lessen their symptoms or side effects. The shared vulnerability model suggests that both

schizophrenia and substance use disorders share a common etiology and pathology. More research is required. However, the available evidence supports a shared vulnerability, in which a shared genetic risk or environmental insult leads to dysfunctions in specific key circuits, such as reward pathways. The result is the increased use of substances during adolescence, as well as the development of schizophrenia.

Complex Partial Epilepsy

Schizophrenia-like psychoses occur more frequently than expected in patients with complex partial seizures, especially seizures involving the temporal lobes. Factors associated with the development of psychosis in these patients include a left-sided seizure focus, medial temporal location of the lesion, and an early onset of seizures. Some psychotic symptoms are similar to symptoms of patients with complex partial epilepsy and may reflect the presence of a temporal lobe disorder when seen in patients with schizophrenia.

Obesity

Patients with schizophrenia appear to be more obese, with higher body mass indexes (BMIs) than age- and gender-matched cohorts in the general population. This obesity is due, at least in part, to the effect of many antipsychotic medications, as well as poor nutritional balance and decreased motor activity. This weight gain, in turn, contributes to an increased risk of cardiovascular morbidity and mortality, an increased risk of diabetes, and other obesity-related conditions such as hyperlipidemia and obstructive sleep apnea.

Diabetes Mellitus

Schizophrenia is associated with an increased risk of type II diabetes mellitus. This comorbidity is probably due, in part, to the association with obesity noted above, but there is also evidence that some antipsychotic medications cause diabetes through a direct mechanism.

Cardiovascular Disease

Many antipsychotic medications have direct effects on cardiac

electrophysiology. Also, obesity, increased rates of smoking, diabetes, and hyperlipidemia, and a sedentary lifestyle all independently increase the risk of cardiovascular morbidity and mortality.

HIV

Patients with schizophrenia appear to have a risk of HIV infection that is 1.5 to 2 times that of the general population. This association is likely due to increased risk behaviors, such as unprotected sex, multiple partners, and increased drug use.

Chronic Obstructive Pulmonary Disease

Rates of chronic obstructive pulmonary disease are increased in schizophrenia compared with the general population. The increased prevalence of smoking is a prominent contributor to this problem; it is not clear whether this is the only one.

Rheumatoid Arthritis

Patients with schizophrenia have a reduced risk of rheumatoid arthritis than is found in the general population. Researchers have replicated this inverse association several times, the significance of which is unknown. GWAS studies also indicate negative genetic correlations, suggesting that they may have shared pathogenesis but differential risks. The exact nature of this relationship remains a mystery and is an ongoing subject of investigation.

COURSE

Onset of Schizophrenia

Premorbid Signs and Symptoms. In theoretical formulations of the course of schizophrenia, premorbid signs and symptoms appear before the prodromal phase of the illness. The differentiation implies that premorbid signs and symptoms exist before the disease process evidences itself and that the prodromal signs and symptoms are parts of the evolving disorder. In the typical, but not invariable, premorbid history of schizophrenia, patients had schizoid or schizotypal personalities characterized as quiet, passive, and

introverted; as children, they had few friends. Preschizophrenic adolescents may have no close friends and no dates and may avoid team sports. They may enjoy watching movies and television, listening to music, or playing computer games to the exclusion of social activities. Some adolescent patients may show a sudden onset of obsessive-compulsive behavior as part of the prodromal picture.

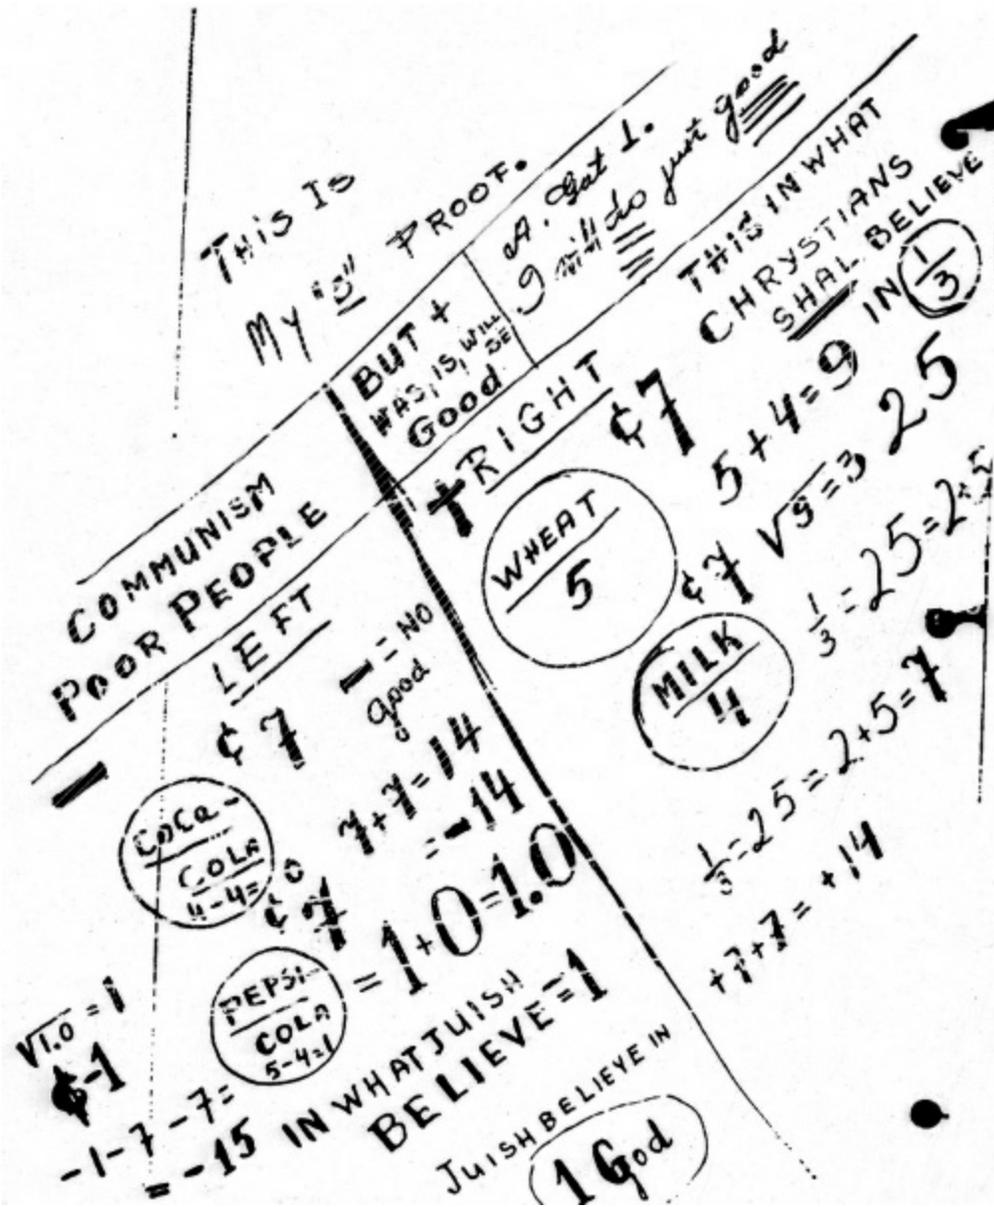
A premorbid pattern of symptoms may be the first evidence of illness, although the importance of the symptoms is usually recognized only retrospectively. Nevertheless, although the family members often believe the disorder began with the first hospitalization, signs and symptoms have often been present for months or even years. The signs may have started with complaints about somatic symptoms, such as headache, back and muscle pain, weakness, and digestive problems. The initial diagnosis may be malingering, chronic fatigue syndrome, or somatic symptom disorder. Family and friends may eventually notice that the person has changed and is no longer functioning well in occupational, social, and personal activities. During this stage, a patient may begin to develop an interest in abstract ideas, philosophy, and the occult or religious questions (Fig. 5-1). Additional prodromal signs and symptoms can include markedly peculiar behavior, abnormal affect, unusual speech, bizarre ideas, and strange perceptual experiences.


FIGURE 5-1
Schizophrenia patient schema. This illustrates his fragmented, abstract, and overly inclusive thinking and preoccupation with religious ideologies and mathematical proofs. (Courtesy of Heinz E. Lehmann.)

Emergence of Symptoms. Characteristically, the symptoms begin in adolescence and are followed by the development of prodromal symptoms in days to a few months. Social or environmental changes, such as going away to college, using a substance, or a relative's death, may precipitate the disturbing symptoms, and the prodromal syndrome may last a year or more before the onset of overt psychotic symptoms.

Duration. The classic course of schizophrenia is one of exacerbations and remissions. After the first psychotic episode, a patient gradually recovers and may then function relatively normally for a long time. Patients usually relapse, however, and the pattern of illness during the first 5 years after the diagnosis generally indicates the patient's course. Further deterioration in the patient's baseline functioning follows each relapse of psychosis. This failure to return to baseline functioning after each relapse was historically thought to be the primary distinction between schizophrenia and mood disorders. Sometimes a clinically observable postpsychotic depression follows a psychotic episode, and the schizophrenia patient's vulnerability to stress is usually lifelong. Positive symptoms tend to become less severe with time, but the socially debilitating negative or deficit symptoms may increase in severity.

An unmarried man, 27 years old, was brought to the mental hospital because he had on several occasions become violent toward his father. For a few weeks, he had hallucinations and heard voices. The voices eventually ceased, but he then adopted a strange way of life. He would sit up all night, sleep all day, and become very angry when his father tried to get him out of bed. He did not shave or wash for weeks, smoked continuously, ate very irregularly, and drank enormous quantities of tea.

In the hospital, he adjusted rapidly to the new environment and was found to be generally cooperative. He showed no marked abnormalities of mental state or behavior, except for his lack of concern for just about anything. He kept to himself as much as possible and conversed little with patients or staff. His personal hygiene had to be supervised by the nursing staff; otherwise, he would quickly become dirty and untidy.

Six years after his admission to the hospital, he is described as shiftless and careless, sullen and unreasonable. He lies on a couch all day long. Although many efforts have been made to get the patient to accept therapeutic work assignments, he refuses to consider any kind of regular occupation. In the summer, he wanders about the hospital grounds or lies under a tree. In the winter, he wanders through the tunnels connecting the various hospital buildings and is often seen stretched out for hours under the warm pipes that carry the steam through the tunnels. (Courtesy of

Heinz E. Lehmann, M.D.)

Although about one-third of all schizophrenia patients have some marginal or integrated social existence, most have lives characterized by aimlessness, inactivity, frequent hospitalizations, and, in urban settings, homelessness and poverty.

Other Disorders

Schizoaffective Disorder. The course of schizoaffective disorder is intermediate between schizophrenia and mood disorders, with a better course and prognosis than for schizophrenia and a worse one than for bipolar disorder or major depressive disorder.

Schizophreniform Disorder. Patients with schizophreniform disorder who do not develop schizophrenia have a better outcome than do patients with schizophrenia.

PROGNOSIS

Having a diagnosis of schizophrenia is associated with a reduction of life expectancy by as much as 20 percent. Persons with schizophrenia have a higher mortality rate from accidents and natural causes than the general population. Institution- or treatment-related variables do not explain the increased mortality rate. However, the higher rate may be related to the fact that the diagnosis and treatment of medical and surgical conditions in schizophrenia patients can be clinical challenges, and in some cases, clinical neglect may be a factor.

Reported remission rates range from 10 to 60 percent, and a reasonable estimate is that 20 to 30 percent of all schizophrenia patients can lead somewhat normal lives. About 20 to 30 percent of patients continue to experience moderate symptoms, and 40 to 60 percent of patients remain significantly impaired by their disorder for their entire lives. Patients with schizophrenia do much poorer than patients with mood disorders, although 20 to 25 percent of mood disorder patients are also severely disturbed at long-term follow-up.

Prognostic Indicators

Several studies have shown that over the 5- to 10-year period after the first psychiatric hospitalization for schizophrenia, only about 10 to 20 percent of patients can be described as having a good outcome. More than 50 percent of patients can be described as having a poor outcome, with repeated hospitalizations, exacerbations of symptoms, episodes of major mood disorders, and suicide attempts. Despite these glum figures, schizophrenia does not always run a deteriorating course, and several factors have been associated with a good prognosis (Table 5-9).

Negative symptoms are rare for schizophreniform disorder, but when they occur, they are considered a poor prognostic feature, and many patients with negative symptoms will later develop schizophrenia.

TREATMENT APPROACH

Although antipsychotic medications are the mainstay of the treatment for schizophrenia, research has found that psychosocial interventions, including psychotherapy, can augment clinical improvement. The complexity of schizophrenia usually renders any single therapeutic approach inadequate to deal with the multifaceted disorder. Psychosocial modalities should be integrated into the drug treatment regimen and should support it. Patients with schizophrenia benefit more from the combined use of antipsychotic drugs and psychosocial treatment than from either treatment used alone.

Table 5-9
Positive and Negative Prognostic Factors for Schizophrenia

Positive Prognostic Factors
  Acute onset
  Female sex
  Living in a developed country

Poor Prognostic Factors
  Insidious onset
  Childhood or adolescent onset

Poor premorbid functioning
Cognitive impairment

Hospitalization

The development of effective antipsychotic drugs and changes in political and popular attitudes toward the treatment and the rights of persons who are mentally ill have dramatically changed the patterns of hospitalization for schizophrenia patients since the mid-1950s. Despite these changes, readmissions after the first hospitalization are frequent, perhaps 40 to 60 percent within 2 years. Patients with schizophrenia occupy about 50 percent of all psychiatric hospital beds and account for about 16 percent of all psychiatric patients who receive any treatment.

In current practice, hospitalization is indicated for diagnostic purposes, for stabilization of medications, for patients' safety because of suicidal or homicidal ideation, and for grossly disorganized or inappropriate behavior, including the inability to take care of basic needs such as food, clothing, and shelter. Establishing an active association between patients and community support systems is also a primary goal of hospitalization.

Short stays of 4 to 6 weeks are just as effective as long-term hospitalizations, and hospital settings with active behavioral approaches produce better results than do custodial institutions. Hospital treatment plans should orient toward practical issues of self-care, quality of life, employment, and social relationships. During hospitalization, clinicians should coordinate with aftercare facilities, including family homes, foster families, board-and-care homes, and halfway houses. Daycare centers and home visits by therapists or nurses can help patients remain out of the hospital for long periods and can improve the quality of their daily lives.

Pharmacotherapy

Patients usually first present for the treatment of acute psychotic symptoms, which require immediate attention. Treatment during the acute phase focuses on alleviating the most severe psychotic symptoms. This phase usually lasts from 4 to 8 weeks.

Antipsychotic medications are considered the mainstay of treatment, both in the acute and maintenance phases of the illness. Table 5-10 lists the

second-generation and commonly used first generation antipsychotics.

Most guidelines recommend starting with a second-generation antipsychotic. Although they are likely the most effective for patients with severe symptoms, and predominantly positive symptoms, they are useful across a broad range of symptoms and severity. There is little guidance for choosing a specific medication: some studies suggest they have individual differences in efficacy. However, the most significant difference between the drugs is in their side effects, and we should consider these carefully when choosing a treatment.

Agitation is a typical symptom in the acute phase. Clinicians have several options for managing agitation that results from psychosis. Antipsychotics and benzodiazepines can result in a relatively rapid calming of patients. With highly agitated patients, intramuscular administration of antipsychotics produces a more rapid effect. An advantage of an antipsychotic is that a single intramuscular injection of a first- or second-generation antipsychotic can often calm the patient without excessive sedation. Low-potency antipsychotics are often associated with sedation and postural hypotension, mainly when administering them intramuscularly. Intramuscular ziprasidone and olanzapine are similar to their oral counterparts in not causing substantial extrapyramidal side effects during acute treatment. This can be a significant advantage over haloperidol or fluphenazine, which can cause frightening dystonias or akathisia in some patients. A rapidly dissolving oral formulation of olanzapine may also be helpful as an alternative to an intramuscular injection.

Benzodiazepines are also useful for agitation during acute psychosis. Lorazepam has the advantage of reliable absorption when administering it either orally or intramuscularly. The use of benzodiazepines may also reduce the amount of antipsychotic that is needed to control psychotic patients.

Treating Side Effects. Patients frequently experience the side effects of an antipsychotic before they experience clinical improvement. Whereas a clinical response may take days or weeks after starting a drug, side effects may begin almost immediately. First-generation antipsychotics most commonly cause extrapyramidal side effects, and in the case of low potency, first-generation antipsychotics, sedation and postural hypotension, whereas second-generation antipsychotics cause weight gain and metabolic

derangements.

EXTRAPYRAMIDAL SIDE EFFECTS. Most first-generation antipsychotics cause extrapyramidal side effects, including parkinsonian symptoms, dystonias, and akathisia. Although less common in second-generation antipsychotics, extrapyramidal effects can still occur.

Clinicians have several alternatives for treating these side effects. These include reducing the dose of the antipsychotic, adding an antiparkinson medication, and changing the patient to a medication that is less likely to cause extrapyramidal side effects. The most effective antiparkinson medications are anticholinergic antiparkinson drugs. However, these medications have additional side effects, including dry mouth, constipation, blurred vision, and, often, memory loss. Also, these medications are often only partially effective, leaving patients with substantial amounts of lingering extrapyramidal side effects. Centrally acting β-blockers, such as propranolol, may help treat akathisia. Most patients respond to dosages between 30 and 90 mg per day.

If prescribing conventional antipsychotics, clinicians may consider prescribing prophylactic antiparkinson medications for patients who are likely to experience disturbing extrapyramidal side effects. These include patients who have a history of extrapyramidal side effect sensitivity and those treated with relatively high doses of high-potency drugs. Prophylactic antiparkinson medications may help when prescribing high-potency drugs for young men, who tend to have an increased vulnerability for developing dystonias. Again, these patients should be candidates for newer drugs.

Some individuals are highly sensitive to extrapyramidal side effects at the dose that is necessary to control their psychosis. For many of these patients, medication side effects may seem worse than the illness itself. These patients should be treated routinely with a medication less likely to cause extrapyramidal side effects. Risperidone may cause extrapyramidal side effects even at low doses—for example, 0.5 mg—but the severity and risk are increased at higher doses—for example, more than 6 mg. Olanzapine and ziprasidone are also associated with dose-related parkinsonism and akathisia.

TARDIVE DYSKINESIA. About 20 to 30 percent of patients on long-term treatment with a first-generation antipsychotic will exhibit symptoms of

tardive dyskinesia. About 3 to 5 percent of young patients receiving a first-generation drug develop tardive dyskinesia each year. The risk in elderly patients is much higher. Although severely disabling dyskinesia is uncommon, it can affect walking, breathing, eating, and talking when it occurs. Individuals who are more sensitive to acute extrapyramidal side effects appear to be more vulnerable to developing tardive dyskinesia. Patients with comorbid cognitive or mood disorders may also be more vulnerable to tardive dyskinesia than those with only schizophrenia.

Table 5-10
Pharmacologic, Formulation and Dosing Information for Second-Generation Antipsychotics and Selected First-Generation Antipsychotics

Antipsychotic	Principal Liver Enzyme Target	Protein Binding	Bio-Availability	Time to Peak Level	Half-Life	CPZ Dose Equivalent, mg	Typical Starting Dose, mg	Typical Dose Range, mg	Maximum Approved Dose, mg	Dose Strength, mg	Route of Administration/Formulation
Second-Generation Antipsychotics											
Partial Dopamine D2 Agonists											
Aripiprazole	2D6 >3A4	>99%	87%	PO: 3–5 hr; IM short 1–3 hr; IM long 5–7 hr	PO: 75 hr; IM long: 30–47 days	7.5	PO: 10–15; IM long (gluteal): 400 with 2 wk oral aripiprazole 10–20	PO: 10–30; IM long (gluteal): 400 every 4 wk	PO: 30; IM long 400	Tablets: 2, 5, 10, 15, 20, 30; Diss: 10, 15; Liquid: 1 mg/mL (except: 30 mg = 25 mL); IM short: 9.75/1.3 mL; IM long q4wk (monohydrate): 300/1.5 mL, 400/1.9 mL, IM long q4 or 6 (882 mg) wk (lauroxil): 441/1.6 mL, 662/2.4 mL, 882/3.2 mL	PO, diss, liquid; IM short, IM long
Brexpiprazole	2D6, 3A4	>99%	95%	4 hr	91 hr	N/A	0.5–1	2–4	4	0.25, 0.5, 1, 2, 3, 4	PO
Cariprazine	3A4 >2D6	91–97%	52% (1 mg)	3–6 hr	2–5 days (didesmethyl-cariprazine: 1–3 wk)	N/A	1.5	1.5–6	6	1.5, 3, 4.5, 6	PO
Dopamine D2—Serotonin 2A Antagonists											
Asenapine	1A2 >3A4	98	35% (<2% if swallowed)	0.5–1.5 hr	First: 6 hr; terminal: 24 hr	7.5	5 bid	10–20	20	Tablets: 5, 10	Sublingual (avoid eating or drinking for 10 min after administration)
Clozapine	1A2 (30%) >2C19 (24%) >3A4 (22%) >2C9 (12%) >2D6 (6%)	97%	50–60%	1.5–2.5 hr	12 hr	50	12.5	50–600	900	Tablets: 25, 50, 100, 200; Diss: 12.5, 25, 100, 150, 200; Liquid: 50 mg/mL	PO, diss, liquid
Iloperidone	2D6 >3A4 >1A2	95%	96%	2–4 hr	18 hr	5	1 mg bid × 1 day, 2 mg × 1 day, then increase 2 mg/d daily to therapeutic dose	12–24	24	Tablets: 1, 2, 4, 6, 8, 10, 12	PO
Lurasidone	3A4	99%	9–19%	1–3 hr	18 hr	25	40–80	40–120	160	Tablets: 20, 40, 80, 120	PO (with ≥350 kcal meal)
Olanzapine	1A2, 2D6, 3A4	93%	60%	PO: 6 hr; IM short: 15–45 min; IM long: 7 days	PO: 30 hr; IM short: 30 hr; IM long: 30 days	5	PO: 5–10; IM long (gluteal): 210/2 wk or 405/4 wk (= oral 10), 300/2 wk (= oral 15 or 20)	PO: 10–20; IM long (gluteal): 150/2 wk or 300/4 wk (= oral 10), 210/2 wk or 405/2 wk (= oral 15), 300/2 wk (= oral 20)	20	Tablets: 2.5, 5, 7.5, 10, 15, 20; Diss: 5, 10, 15, 20; IM short: 10/2 mL; IM long q2 or 4 wk: 150/1.3 mL, 210/1.3 mL, 300/1.8 mL, 405/2.3 mL	PO, diss; IM short, IM long

Paliperidone	<10% first-pass hepatic clearance	74%	28%	PO: 24 hr; IM long: 13 days	PO: 23 hr; IM long: 25–49 days	3	PO: 6; IM long: 234 mg into deltoid day 1, then 156 mg day 8, then 39–234 into deltoid or gluteus every 4 wk	PO: 3–12; IM long (deltoid or gluteal): 117–234 every 4 wk	12	Tablets: 1.5, 3, 6, 9; IM long q4wk: 39 0.25 mL, 78 0.5 mL, 117/0.75 mL, 156/1 mL, 234/1.5 mL; IM long q12wk: 273 0.875 mL, 410/1.315 mL, 546/1.75 mL, 819/2.625 mL	PO (ER); IM long
Quetiapine	3A4	83%	100%	IR: 1.5 hr; XR: 6 hr	6–7 hr	75	IR: 25–100; XR: 200–300	IR: 150–750; XR: 400–800	800	Tablets: IR: 25, 50, 100, 200, 300, 400; XR: 50, 150, 200, 300, 400	PO (IR, XR)
Risperidone	2D6 >3A4	90%	70%	3 hr	3 hr	2	PO: 2; IM long (deltoid or gluteal): 25 with 3 wk oral risperidone	PO: 2–8; IM long (deltoid or gluteal): 12.5–50 into deltoid or gluteal muscle every 2 wk	16	Tablets: 0.25, 0.5, 1, 2, 3, 4; Diss: 0.5, 1, 2, 3, 4; Liquid: 1 mg/mL; IM long q2w: 12.5/1 mL, 25/2 mL, 37.5/2 mL, 50/2 mL	PO, diss, liquid; IM long
Ziprasidone	Aldehyde oxidase (2/3) >3A4 (1/3)	>99%	60%	PO: 6–8 hr; IM short ≤60 min	PO: 7 hr; IM short: 2–5 hr	60	20–40 bid	80–160	160	Tablets: 20, 40, 60, 80 IM short: 20/1 mL	PO (with ≥500 kcal meal), IM short
First-Generation Antipsychotics (Dopamine D2 Antagonists)											
Chlorpromazine	2D6	>90	20%	2–4 hr	30 hr	100	PO: 25–100 mg; IM short: 25, followed by 25–50 mg as needed after 1–4 hr	PO: 200–800; IV/IM short: 400 mg every 4–6 hr	2,000	Tablets: 10, 25, 50, 100, 200; Spansule: 30, 75, 150; Syrup: 5 mL = 10 mg; Liquid: 25 mg/5 mL; IM short: 25/mL; Supp: 25, 100	PO, syrup; IM short, IV, rectal suppository
Fluphenazine	1A2	>90	<50%	PO: 2 hr; IM long: 8–10 hr	PO: 14–16 hr; IM long: 14 days	2	PO: 2.5–10 in 2–3 divided doses	PO: 1–5 in 2–3 divided doses; IM long (deltoid or gluteal): 12.5–25 mg every 2–4 wk	40	Tablets: 1, 2.5, 5, 10; Liquid: 2.5 or 5/mL; IM long 25 mg/mL	PO; IM long
Haloperidol	3A4	92%	60%–70%	PO: 2–6 hr; IM short 10–20 min; IM long: 6–7 days	PO: 18 hr; IM short 2–5 hr; IM long: 3 wk	2	PO: 1–2; IM short: 2–5 mg every 4–8 hr as needed; IM long (deltoid or gluteal): 10–20 times the oral dose every 4 wk (≤100)	PO: 2–10; IM long (deltoid or gluteal): 10–15 times the oral dose every 4 wk (≤100)	PO: 60; IM long: 100	Tablets: 0.5, 1, 2, 5, 10, 20 Liquid 2 or 10 mg/mL; IM short: 5; IM long q4wk: 50 mg/mL, 100 mg/mL	PO; IM short, IM long
Perphenazine	2D6	>90%	40%	1–3 hr	9–12 hr	10	Inpatient: 8–16 divided in 2–3 doses; Outpatient: 4–8 divided in 3 doses	8–32	64	2, 4, 8, 16	PO

*Chlorpromazine dose equivalents i.e., dose given in the table is equivalent to 100 mg of chlorpromazine.
†Doses need to be individualized based on efficacy and tolerability.
CPZ, chlorpromazine; Diss, dissolvable tablet; ER, extended release; IM, intramuscular; IR, immediate release; IV, intravenous; N/A, not available; q, every; PO, oral; Supp, suppository; XR, extended release.
Source: Package insert information for each medication.

The abnormal movements usually begin while the patient is receiving an antipsychotic or within 4 weeks of discontinuing an oral antipsychotic or 8 weeks after the withdrawal of a depot antipsychotic.

There is a lower risk of tardive dyskinesia with new-generation drugs. However, there still is some risk of tardive dyskinesia with newer drugs.

Recommendations for preventing and managing tardive dyskinesia include: (1) using the lowest effective dose of antipsychotics; (2) prescribing cautiously with children, elderly patients, and patients with mood disorders; (3) examining patients regularly for evidence of tardive dyskinesia; (4) considering alternatives to the current antipsychotic and considering dosage reduction when observing tardive dyskinesia; and (5) considering several options if the tardive dyskinesia worsens, including discontinuing the antipsychotic or switching to a different drug. Clozapine is effective in reducing severe tardive dyskinesia or tardive dystonia.

OTHER SIDE EFFECTS. Sedation and postural hypotension can be significant side effects for patients treated with low-potency first-generation drugs, such as perphenazine. These effects are often most severe during the initial dosing

of these medications. As a result, patients treated with these medications—or with clozapine—may require weeks to reach a therapeutic dose. Although most patients develop tolerance to sedation and postural hypotension, sedation may continue to be a problem. In these patients, daytime drowsiness may interfere with a patient's attempts to return to community life.

All antipsychotics elevate prolactin levels, which can result in galactorrhea and irregular menses. Long-term elevations in prolactin and the resultant suppression in gonadotropin-releasing hormone can cause suppression in gonadal hormones. These, in turn, may have effects on libido and sexual functioning. There is also concern that elevated prolactin may cause decreases in bone density and lead to osteoporosis. The concerns about hyperprolactinemia, sexual functioning, and bone density are based on experiences with prolactin elevations related to tumors and other causes. It is unclear if these risks are also associated with the lower elevations that occur with prolactin-elevating drugs.

HEALTH MONITORING IN PATIENTS RECEIVING ANTIPSYCHOTICS. Because of the effects of the second-generation antipsychotics on insulin metabolism, psychiatrists should monitor several health indicators, including BMI, fasting blood glucose, and lipid profiles. We should weigh patients and calculate their BMIs for every visit for at least 6 months after a medication change.

Clozapine. Clozapine is considered the most effective of antipsychotics, particularly in patients who have been unresponsive to other treatments. However, it is a challenging drug to administer, given its risk of both severe side effects (agranulocytosis in approximately 0.3 percent of those taking it, seizures in as high as 5 percent of those on doses above 600 mg, and, more rarely, myocarditis) and common ones (hypersalivation, sedation, tachycardia, weight gain, and postural hypotension). The concerns over agranulocytosis have resulted in a monitoring system in the United States in which patients who receive clozapine must be in a program of weekly blood monitoring for the first 6 months and biweekly monitoring for the next 6 months, and monthly after that.

These limitations have relegated clozapine to a later treatment option, and most guidelines recommend considering it after a patient has failed at least two other antipsychotic trials.

Duration and Prophylaxis

In the stable or maintenance phase, the illness is in a relative stage of remission. The goals during this phase are to prevent psychotic relapse and to assist patients in improving their level of functioning. Newer medications, with a substantially reduced risk of tardive dyskinesia, have diminished one of the major concerns about long-term treatment. During this phase, patients are usually in a relative state of remission with only minimal psychotic symptoms. Stable patients who are maintained on an antipsychotic have a much lower relapse rate than patients who have their medications discontinued. Data suggest that 16 to 23 percent of patients receiving treatment will experience a relapse within 1 year, and 53 to 72 percent will relapse without medications.

We should maintain patients experiencing a first episode of psychosis for at least a year. However, such patients still have a high chance of relapsing at least once over the following 5 years, and some experts believe that 1 year is inadequate. This is a particular concern when patients have achieved functional employment status or are involved in educational programs because they have a lot to lose if they experience another psychotic decompensation.

For patients experiencing two or more episodes, most experts recommend that we consider indefinite treatment.

Acute Treatment Failures

Addressing Noncompliance. Noncompliance with long-term antipsychotic treatment is very high. An estimated 40 to 50 percent of patients become noncompliant within 1 or 2 years. Long-acting injectable antipsychotics were developed to help improve adherence, particularly in patients likely to discontinue daily oral medications. Although there is some controversy in the literature, the weight of data suggests that long-term depot formulations do help adherence and decrease relapse, mainly when considered in real-world settings.

When beginning long-acting drugs, some oral supplementation is necessary while achieving peak plasma levels. Fluphenazine, haloperidol, risperidone, paliperidone, aripiprazole, and olanzapine have long-acting

injectable formulations.

There are several advantages to using long-acting injectable medication. Clinicians quickly know when noncompliance occurs and have some time to initiate appropriate interventions before the medication effect dissipates. Also, there is less day-to-day variability in blood levels, making it easier to establish a minimum effective dose. Finally, many patients prefer it to managing daily dosage schedules.

Selecting Second Treatment Options. When giving patients with acute schizophrenia an antipsychotic medication, approximately 60 percent will improve to the extent that they will achieve a complete remission or experience only mild symptoms. The remaining 40 percent of patients will improve but still demonstrate variable levels of positive symptoms that are resistant to the medications. One meta-analysis of available studies found that patients who did not show at least some response to treatment by the second week were less likely to benefit from the drug, and a treatment change may be the best option.

Rather than categorizing patients into responders and nonresponders, it is more accurate to consider the degree to which the illness improves with medication. Some resistant patients are so severely ill that they require chronic institutionalization. Others respond to an antipsychotic with substantial suppression of their psychotic symptoms but demonstrate persistent symptoms, such as hallucinations or delusions.

Before considering a patient a poor responder to a particular drug, it is vital to assure that they received an adequate trial of the medication. A 4- to 6-week trial on an adequate dose of an antipsychotic represents a reasonable trial for most patients. Patients who demonstrate even a mild amount of improvement during this period may continue to improve at a steady rate for 3 to 6 months. It may be helpful to confirm that the patient is receiving an adequate amount of the drug by monitoring the plasma concentration; that said, most of the accepted levels pertain to first-generation drugs, and there is less rationale for obtaining levels in patients who receive second-generation drugs. However, in any patient, a deficient plasma concentration may indicate that the patient has been noncompliant or, more commonly, only partially compliant. It may also suggest that the patient is a rapid metabolizer of the antipsychotic or is not absorbing the drug adequately. Under these conditions,

raising the dose may be helpful. If the level is relatively high, clinicians should consider whether side effects may be interfering with therapeutic response.

If the patient is responding poorly, one may increase the dose above the usual therapeutic level; however, higher than recommended doses usually do not improve response. Changing to another drug is preferable.

As discussed earlier, clozapine is useful for patients who respond poorly to other antipsychotics. Double-blind studies comparing clozapine with other antipsychotics indicated that clozapine had the most evident advantage over conventional drugs in patients with the most severe psychotic symptoms, as well as in those who had previously responded poorly to other antipsychotics.

Researchers and clinicians have tried several adjunctive medications, most with mixed success. These include lamotrigine, mirtazapine, donepezil, D-alanine, D-serine, estradiol, memantine, and allopurinol.

Other Somatic Treatments

Researchers have studied electroconvulsive therapy (ECT) in both acute and chronic schizophrenia. Studies in recent-onset patients indicate that ECT is about as effective as antipsychotic medications and more effective than psychotherapy. Other studies suggest that supplementing antipsychotic medications with ECT is more effective than antipsychotic medications alone. Antipsychotic medications should be administered during and after ECT treatment.

Some initial studies have suggested neuromodulation, using transcranial magnetic stimulation (TMS) or transcranial direct current stimulation (tDCS), may be useful for treating hallucinations or negative symptoms.

Although we no longer consider psychosurgery to be appropriate treatment, some research centers practice it on a limited experimental basis for severe, intractable cases.

Psychosocial Therapy

Psychotherapy is considered an essential part of treatment for schizophrenia, and patients who receive psychotherapy along with medications tend to have better adherence to therapy, less negative symptoms, and better overall functioning.

Currently, there is no convincing evidence to suggest that any single psychotherapeutic approach is preferable to another, although all tend to emphasize structured approaches rather than open-ended, exploratory methods. Psychosocial therapies include a variety of methods to increase social abilities, self-sufficiency, practical skills, and interpersonal communication in schizophrenia patients. The goal is to enable persons who are severely ill to develop social and vocational skills for independent living. Many sites use these approaches, including hospitals, outpatient clinics, mental health centers, day hospitals, and home or social clubs.

Cognitive Behavioral Therapy. Cognitive-behavioral therapy (CBT) has been used in schizophrenia patients to improve cognitive distortions, reduce distractibility, and correct errors in judgment. There are reports of ameliorating delusions and hallucinations in some patients using this method. Patients who might benefit generally have some insight into their illness, and clinicians usually use this approach after treating an acute psychotic episode. The approach generally incorporates cognitive restructuring, self-monitoring, and graded coping skills. Although at least one randomized controlled study showed a benefit for CBT as a sole treatment, most experts recommend it in combination with antipsychotic treatment.

Social Skills Training. Social skills training, also called behavioral skills therapy, can be directly supportive and useful for a patient. In addition to the psychotic symptoms seen in patients with schizophrenia, other noticeable symptoms involve the way the person relates to others, including poor eye contact, unusual delays in response, odd facial expressions, lack of spontaneity in social situations, and inaccurate perception or lack of perception of emotions in other people. Behavioral skills training addresses these behaviors through the use of videotapes of others and the patient, role-playing in therapy, and homework assignments for practicing the specific skills. Social skills training can reduce relapse rates and the need for hospitalization.

Group Therapy. Group psychotherapy for patients with schizophrenia can help improve social functioning and decrease negative symptoms. Group therapy for persons with schizophrenia generally focuses on real-life plans,

problems, and relationships. Groups may be behaviorally oriented, psychodynamically or insight-oriented, or supportive. Some investigators doubt that dynamic interpretation and insight therapy are valuable for typical patients with schizophrenia. However, group therapy is effective in reducing social isolation, increasing the sense of cohesiveness, and improving reality testing for patients with schizophrenia. Groups led in a supportive manner appear to be most helpful for schizophrenia patients.

Family-Oriented Therapies. Family therapy can be a significant adjunct to treatment and reduces relapse and rehospitalization rates compared to patients receiving standard care. Such therapy generally includes practical approaches such as psychoeducation and problem-solving training. Because patients with schizophrenia are often discharged in an only partially remitted state, a family to which a patient returns can often benefit from a brief but intensive (as often as daily) course of family therapy. The therapy should focus on the immediate situation and should include identifying and avoiding potentially troublesome situations. When problems do emerge with the patient in the family, the aim of the therapy should be to resolve the problem quickly.

In wanting to help, family members often encourage a relative with schizophrenia to resume regular activities too quickly, both from ignorance about the disorder and from denial of its severity. Without being overly discouraging, therapists must help both the family and the patient understand and learn about schizophrenia and must encourage discussion of the psychotic episode and the events leading up to it. Ignoring the psychotic episode, a common occurrence, often increases the shame associated with the event and does not exploit the freshness of the episode to understand it better. Psychotic symptoms often frighten family members, and talking openly with the psychiatrist and with the relative with schizophrenia often eases all parties. Therapists can direct later family therapy toward the long-range application of stress-reducing and coping strategies and the patient's gradual reintegration into everyday life.

Therapists must control the emotional intensity of family sessions with patients with schizophrenia. The excessive expression of emotion during a session can damage a patient's recovery process and undermine potentially successful future family therapy. Several studies have shown that family

therapy is especially useful in reducing relapses.

Case Management and Assertive Community Treatment. Because a variety of professionals with specialized skills, such as psychiatrists, social workers, and occupational therapists, among others, are involved in a treatment program, it is helpful to have one person aware of all the forces acting on the patient. The case manager helps coordinate this and ensures that the patient keeps appointments and complies with treatment plans. The case manager may also make home visits and even accompany the patient to work. The success of the program depends on the educational background, training, and competence of the individual case manager, which vary. Most important is maintaining a small caseload (less than 20 cases per manager), which can be challenging for overtaxed and underfunded systems.

The Assertive Community Treatment (ACT) program was initially developed by researchers in Madison, Wisconsin, in the 1970s, for the delivery of services for persons with chronic mental illness. Patients are assigned to one multidisciplinary team (e.g., case manager, psychiatrist, nurse, general physicians). The team has a fixed caseload of patients and delivers all services when and where needed by the patient, 24 hours a day, 7 days a week. ACT is a mobile and intensive intervention that provides treatment, rehabilitation, and support activities. These include home delivery of medications, monitoring of mental and physical health, in vivo social skills, and frequent contact with family members. There is a high staff-to-patient ratio (1:12). ACT programs can effectively decrease the risk of rehospitalization for persons with schizophrenia, but they are labor-intensive and expensive programs to administer.

Although the evidence is low in quality, there is some evidence to suggest that intensive case management can reduce hospitalization time and increase adherence to treatment. Intensive case management approaches seem to be most effective when they incorporate ACT.

Individual Psychotherapy. Studies of the effects of individual psychotherapy in the treatment of schizophrenia suggest that therapy is helpful and that the effects are additive to those of pharmacologic treatment. In psychotherapy with a schizophrenia patient, developing a therapeutic relationship that the patient experiences as safe is critical. The therapist's

reliability, the emotional distance between the therapist and the patient, and the genuineness of the therapist as interpreted by the patient all affect the therapeutic experience. When considering psychotherapy for a patient with schizophrenia, we should think in decades, rather than sessions, months, or even years.

The best predictor of psychotherapy outcome is probably the strength of the therapeutic alliance. Schizophrenia patients who can form a positive therapeutic alliance are likely to remain in psychotherapy, to remain compliant with their medications, and to have good outcomes at 2-year follow-up evaluations.

The relationship between clinicians and patients differs from that encountered in the treatment of nonpsychotic patients. Establishing a relationship is often challenging. Persons with schizophrenia are desperately lonely, yet defend against closeness and trust; they are likely to become suspicious, anxious, or hostile or to regress when someone attempts to draw close.

Therapists should scrupulously respect a patient's distance and privacy and should demonstrate simple directness, patience, sincerity, and sensitivity to social conventions in preference to premature informality and the condescending use of first names. The patient is likely to perceive exaggerated warmth or professions of friendship as attempts at bribery, manipulation, or exploitation. In the context of a professional relationship, however, flexibility is essential in establishing a working alliance with the patient.

Vocational Therapy and Supported Employment. A variety of methods and settings can help patients regain old skills or develop new ones. These include sheltered workshops, job clubs, and part-time or transitional employment programs. Enabling patients to become gainfully employed is both a means toward and a sign of recovery. Many schizophrenia patients are capable of performing high-quality work despite their illness. Others may exhibit exceptional skill or even brilliance in a limited field as a result of some distinctive aspects of their disorder.

Supported employment focuses on helping patients to obtain competitive employment as opposed to sheltered workshops. It has strong data for helping patients to find and maintain jobs; it also is associated with less need for

treatment and improved self-esteem. It is less consistently associated with overall disease outcomes.

Art Therapy. Many schizophrenia patients benefit from art therapy, which provides them with an outlet for their constant bombardment of imagery. It helps them communicate with others and share their inner, often frightening world with others.

Cognitive Remediation. Cognitive remediation or cognitive training is a behavioral therapy that attempts to improve cognitive processes. It uses computer-generated exercises to influence neural networks to improve cognition, including working memory. This can then improve social functioning. One metanalysis determined that its effect size is in the medium range.

National Alliance on Mental Illness (NAMI). The NAMI and similar organizations offer support groups for family members and friends of patients who are mentally ill and for patients themselves. These organizations offer emotional and practical advice about obtaining care in the sometimes complex health care delivery system and are useful sources to which to refer family members. NAMI has also waged a campaign to destigmatize mental illness and to increase government awareness of the needs and rights of persons who are mentally ill and their families.

THE EPIDEMIOLOGY OF THE DISORDERS

Incidence and Prevalence

The worldwide lifetime prevalence of schizophrenia is about 0.7 percent. One meta-analysis of 101 prevalence rates published between 1990 and 2015 found that the mean global lifetime prevalence of psychotic disorders worldwide was 7.49 per 1,000 individuals. However, there was an extensive range across studies representing an approximately five-fold difference. These variations could largely be accounted for by the different methodologic approaches of different studies, including different populations and settings studied, different diagnostic criteria and diagnoses included, and differences in the study quality.

Table 5-11 lists some of the major epidemiologic studies of schizophrenia.

In the United States, about 0.05 percent of the total population is treated for schizophrenia in any single year. Perhaps only one-half of all patients with schizophrenia will obtain treatment, despite the severity of the disorder.

Sex

Schizophrenia is equally prevalent in men and women. The two sexes differ in the onset and course of illness. The onset of schizophrenia is earlier for men. Also, more than half of all male schizophrenia patients, but only one-third of all female schizophrenia patients, will be hospitalized for the disorder before age 25 years. Some studies have indicated that men are more likely to be impaired by negative symptoms than are women and that women are more likely to have better social functioning than are men before disease onset. In general, the outcome for female schizophrenia patients is better than that for male schizophrenia patients.

Table 5-11
Selected Prevalence Studies of Schizophrenia

Author	Country	Population	Method	Prevalence per 1,000 Population at Risk
Brugger (1931)	Germany	Area in Thuringia (*n* = 37,561); age 10+ yr	Census; interview of sample	2.4
Strömgren (1938); Bøjholm and Strömgren (1989)	Denmark	Island population (*n* = 50,000)	Census interviews; repeat census	3.9 → 3.3
Böök (1953); Böök et al. (1978)	Sweden	Genetic isolate (*n* = 9,000); age 15–50 yr	Census interviews; repeat census	9.5 → 17.0

Age

In the United States, the peak ages of onset are between 10 and 25 years for men and 25 and 35 years for women. Unlike men, women display a bimodal age distribution, with a second peak occurring in middle age—approximately 3 to 10 percent of women with schizophrenia present with disease onset after age 40 years. About 90 percent of patients in treatment for schizophrenia are between 15 and 55 years old. The onset of schizophrenia before age 10 years or after age 60 years is scarce. Late-onset schizophrenia refers to the occurrence of the disorder after age 45 years.

Other Factors Affecting Epidemiology

Seasonality of Birth. Persons who develop schizophrenia are more likely to have been born in the winter or early spring. In the Northern Hemisphere, including the United States, persons with schizophrenia are more often born in the months from January to April. In the Southern Hemisphere, persons with schizophrenia are more often born in the months from July to September.

Maternal Factors Affecting the Fetus. Complications during delivery, maternal malnutrition during pregnancy, as well as other illnesses, appear to be risk factors for schizophrenia.

Early Life Experiences. Childhood trauma, social isolation, and other types of deprivation also seem to be risk factors.

Urban Upbringing. Several studies, mainly from the 1990s, have suggested that being born or living in a city is a risk for schizophrenia. This has been reported in various countries. The relationship appears to be more convincing for being raised in rather than being born in a city. The relationship may be "dose-related," meaning that the larger the city, the higher the risk.

Cannabis. There is an association between cannabis use and psychosis, and the use of cannabis may increase the risk of schizophrenia by as much as 40%, particularly in heavy users.

Cognitive Deficits May also be a Risk Factor. More recent research has suggested that cognitive deficits, such as poor verbal learning and memory and slower processing speed, can be a predictor of impending psychosis.

Other Psychotic Disorders

Schizoaffective disorder is less common than schizophrenia, possibly in the range of 0.5 to 0.8 percent, although the varying criteria used in different studies limits the findings. The sex differences are more typical of mood disorders in which there is a higher ratio of women than men having the depressed subtype but a similar ratio with the bipolar subtype. The bipolar

subtype may be more common in younger persons than in adults, who are more commonly depressed. As with schizophrenia, women tend to get it later than men.

We know little about the incidence, prevalence, and sex ratio of schizophreniform disorder. It appears to be about half as common as schizophrenia, more common in men, and most common in adolescents and young adults. The relatives of patients with schizophreniform disorder are more likely to have mood disorders than are the relatives of patients with schizophrenia. Many of those mood disorders include psychotic symptoms, however.

THE NEUROBIOLOGY OF THE DISORDER

Anatomic Findings

In the 19th century, neuropathologists failed to find a neuropathologic basis for schizophrenia, and thus they classified schizophrenia as a functional disorder. By the end of the 20th century, however, researchers had better tools and made significant strides in revealing a potential neuropathologic basis for schizophrenia.

Cerebral Ventricles. Computed tomography (CT) scans of patients with schizophrenia have consistently shown lateral and third ventricular enlargement and some reduction in cortical volume. Reduced volumes of cortical gray matter have been demonstrated during the earliest stages of the disease. Several investigators have attempted to determine whether the abnormalities detected by CT are progressive or static. Some studies have concluded that the lesions observed on CT scan are present at the onset of the illness and do not progress. Other studies, however, have concluded that the pathologic process visualized on CT scan continues to progress during the illness. Thus, whether an active pathologic process is continuing to evolve in schizophrenia patients is still uncertain.

Reduced Symmetry. There is a reduced symmetry in several brain areas in schizophrenia, including the temporal, frontal, and occipital lobes. This reduced symmetry is believed by some investigators to originate during fetal life and to be indicative of a disruption in brain lateralization during

neurodevelopment.

Limbic System. Because of its role in controlling emotions, researchers believe that the limbic system is involved in the pathophysiology of schizophrenia. Studies of postmortem brain samples from schizophrenia patients have shown a decrease in the size of the region, including the amygdala, the hippocampus, and the parahippocampal gyrus. This neuropathologic finding agrees with the observation made by magnetic resonance imaging studies of patients with schizophrenia. The hippocampus is not only smaller in size in schizophrenia but is also functionally abnormal, as indicated by disturbances in glutamate transmission. Brain tissue sections also show the disorganization of the neurons within the hippocampus in some patients with schizophrenia.

Prefrontal Cortex. There is considerable evidence from postmortem brain studies that support anatomical abnormalities in the prefrontal cortex in schizophrenia. Functional deficits in the prefrontal brain imaging region have also been demonstrated. Of interest, several symptoms of schizophrenia mimic those found in persons with prefrontal lobotomies or frontal lobe syndromes.

Thalamus. Some studies of the thalamus show evidence of volume shrinkage or neuronal loss in particular subnuclei. The medial dorsal nucleus of the thalamus, which has reciprocal connections with the prefrontal cortex, has been reported to contain a reduced number of neurons. The total number of neurons, oligodendrocytes, and astrocytes is reduced by 30 to 45 percent in schizophrenia patients. This putative finding does not appear to be due to the effects of antipsychotic drugs, because the volume of the thalamus is similar in size between patients with schizophrenia treated chronically with medication and neuroleptic-naive subjects.

Basal Ganglia and Cerebellum. The basal ganglia and cerebellum have been of theoretical interest in schizophrenia for at least two reasons. First, many patients with schizophrenia show odd movements, even in the absence of medication-induced movement disorders. The odd movements can include an awkward gait, facial grimacing, and stereotypies. Because the basal

ganglia and cerebellum are involved in the control of movement, disease in these areas is implicated in the pathophysiology of schizophrenia. Second, the movement disorders involving the basal ganglia (e.g., Huntington disease, Parkinson disease) are the ones most commonly associated with psychosis. Neuropathologic studies of the basal ganglia have produced variable and inconclusive reports about cell loss or the reduction of volume of the globus pallidus and the substantia nigra. Studies have also shown an increase in the number of D_2 receptors in the caudate, putamen, and the nucleus accumbens.

The question remains, however, whether the increase is secondary to the patient having received antipsychotic medications. Some investigators have begun to study the serotonergic system in the basal ganglia; the clinical usefulness of antipsychotic drugs that are serotonin antagonists suggests a role for serotonin in psychotic disorders.

Physiologic Findings

Functional Imagining. PET studies have shown a variety of neurotransmitter abnormalities, including increased dopamine levels in the ventral striatum and reduced levels in the frontal cortex.

Studies using magnetic resonance spectroscopy have demonstrated increased glutamate levels, particularly in the prefrontal and medial temporal areas. Furthermore, concentrations of N-acetyl aspartate, a marker of neurons, were lower in the hippocampus and frontal lobes of patients with schizophrenia.

Electrophysiologic Findings. Electroencephalographic studies indicate that many schizophrenia patients have abnormal records, increased sensitivity to activation procedures (e.g., frequent spike activity after sleep deprivation), decreased alpha activity, increased theta and delta activity, possibly more epileptiform activity than usual, and possibly more left-sided abnormalities than usual. Schizophrenia patients also exhibit an inability to filter out irrelevant sounds and are extremely sensitive to background noise. The flooding of sound that results makes concentration difficult and may be a factor in the production of auditory hallucinations. This sound sensitivity may be associated with a genetic defect.

Evoked Potentials. A large number of abnormalities are seen in the evoked potential of patients with schizophrenia. The P300 is most studied; it is a large, positive evoked-potential wave that occurs about 300 milliseconds after a sensory stimulus is detected. The primary source of the P300 wave is likely in the limbic system structures of the medial temporal lobes. In patients with schizophrenia, the P300 is statistically smaller than in comparison groups. Abnormalities in the P300 wave are also common in children who, because they have affected parents, are at high risk for schizophrenia. Whether the characteristics of the P300 represent a state or a trait phenomenon remains controversial. Other evoked potentials reported to be abnormal in patients with schizophrenia are the N100 and the contingent negative variation. The N100 is a negative wave that occurs about 100 milliseconds after a stimulus, and the contingent negative variation is a slowly developing, negative-voltage shift following the presentation of a sensory stimulus that is a warning for an upcoming stimulus. The evoked-potential data likely indicates that, although patients with schizophrenia are unusually sensitive to a sensory stimulus (larger early evoked potentials), they compensate for the increased sensitivity by blunting the processing of information at higher cortical levels (indicated by smaller late evoked potentials).

Eye Movement Dysfunction. The inability to follow a moving visual target accurately is the defining basis for the disorders of smooth visual pursuit and disinhibition of saccadic eye movements seen in patients with schizophrenia. Eye movement dysfunction may be a trait marker for schizophrenia; it is independent of drug treatment and clinical state and also occurs in first-degree relatives of probands with schizophrenia. Various studies have reported abnormal eye movements in 50 to 85 percent of patients with schizophrenia compared with about 25 percent in psychiatric patients without schizophrenia and fewer than 10 percent in nonpsychiatrically ill control participants.

Prepulse Inhibition Deficits. Prepulse inhibition refers to a dysfunction of sensorimotor gating. Usually, a prepulse or weak stimulus, such as a noise, can decrease the startle reaction to a subsequent more substantial stimulus, such as a louder noise. As early as the 1970s, researchers found that patients

with schizophrenia lacked this normal inhibition, and this was later found in the relatives of schizophrenia patients as well. Dopamine regulates sensorimotor gating, which adds additional support for the importance of dopamine in schizophrenia.

Neurotransmitters and Receptors

Excessive dopamine release in patients with schizophrenia is associated with the severity of positive psychotic symptoms. Positron emission tomography studies of dopamine receptors have shown that patients with schizophrenia have increases in subcortical synaptic dopamine content and increased subcortical synthesis capacity. These appear localized to the area of the associative striatum. These abnormalities, particularly increased subcortical synaptic dopamine content, are associated with the positive symptoms of schizophrenia and positive treatment response. However, the dopamine abnormalities are not merely due to the symptoms, as these abnormalities precede the onset of illness. They also occur in individuals considered to be at high risk for schizophrenia.

In addition to dopamine, there are increased levels of glutamate and decreased levels of γ-aminobutyric acid (GABA). Some patients with schizophrenia show a loss of GABAergic neurons in the hippocampus.

Postmortem studies in schizophrenia have demonstrated decreased muscarinic and nicotinic receptors in the caudate-putamen, hippocampus, and selected regions of the prefrontal cortex. These receptors play a role in the regulation of neurotransmitter systems involved in cognition, which is impaired in schizophrenia.

As a result of these neurotransmitter alterations, there are alterations in a variety of receptors. For example, N-methyl-D-aspartate (NMDA) receptors appear to hypofunction as a result of glutamate and dopamine excesses.

Psychoneuroimmunology

Several immunologic abnormalities are associated with patients who have schizophrenia. The abnormalities include decreased T-cell interleukin-2 production, reduced number and responsiveness of peripheral lymphocytes, abnormal cellular and humoral reactivity to neurons, and the presence of brain-directed (antibrain) antibodies. The data can be interpreted variously as

representing the effects of a neurotoxic virus or an endogenous autoimmune disorder.

The observation further strengthens the hypothesis that several autoimmune diseases can cause psychosis, such as systemic lupus encephalitis. Similarly, some types of immune encephalitis, such as anti-NMDA receptor encephalitis, can cause a psychotic illness that resembles schizophrenia, at least early in the illness.

Psychoneuroendocrinology

Many reports describe neuroendocrine differences between groups of patients with schizophrenia and groups of control subjects. For example, the results of the dexamethasone-suppression test are abnormal in various subgroups of patients with schizophrenia, although the test lacks practical or predictive value.

Some data suggest decreased concentrations of luteinizing hormone or follicle-stimulating hormone, perhaps correlated with age of onset and length of illness. Two additional reported abnormalities may correlate with the presence of negative symptoms: a blunted release of prolactin and growth hormone on gonadotropin-releasing hormone or thyrotropin-releasing hormone stimulation and a blunted release of growth hormone on apomorphine stimulation.

Infections

The support for infections being operative in schizophrenia is mostly indirect. As already mentioned, persons with schizophrenia may be more likely to be born in the winter months, thus suggesting a season-specific risk factor such as a virus (there are other explanations, however, such as changes in diet).

Epidemiologic data show a high incidence of schizophrenia after prenatal exposure to influenza during several epidemics of the disease. Some studies show that the frequency of schizophrenia increases after exposure to influenza during the second trimester of pregnancy. Influenza is, of course, more prevalent during the winter than other seasons. Other data supporting a viral hypothesis are an increased number of physical anomalies at birth, an increased rate of pregnancy and birth complications, seasonality of birth consistent with a viral infection, geographical clusters of adult cases, and

seasonality of hospitalizations.

Viral theories stem from the fact that several specific viral theories have the power to explain the particular localization of pathology necessary to account for a range of manifestations in schizophrenia without overt febrile encephalitis.

Environmental Factors

In addition to infections, a variety of other factors, particularly in the prenatal period, can contribute a small but significant risk for schizophrenia. These include birth complications, trauma after delivery, nutritional deficiencies, and other factors that may negatively affect healthy development.

Our Understanding of the Genetics of Schizophrenia

Studies of Inheritance Patterns. At least as early as the 1930's, twin and family studies demonstrated that schizophrenia was an inherited disorder. The heritability of schizophrenia is estimated to be about 60 to 80 percent.

The likelihood of a person having schizophrenia correlates with the closeness of the relationship to an affected relative (e.g., first- or second-degree relative). In the case of monozygotic twins who have an identical genetic endowment, there is an approximately 50 percent concordance rate for schizophrenia. This rate is four to five times the concordance rate in dizygotic twins or the rate of occurrence found in other first-degree relatives (i.e., siblings, parents, or offspring). The role of genetic factors is further reflected by the drop-off in the occurrence of schizophrenia among second- and third-degree relatives, in whom one would hypothesize a decreased genetic loading. The finding of a higher rate of schizophrenia among the biologic relatives of an adopted-away person who develops schizophrenia, compared with the adoptive, nonbiologic relatives who raise the patient, provides further support to the genetic contribution to the etiology of schizophrenia.

Nevertheless, the monozygotic twin data demonstrate the fact that individuals who are genetically vulnerable to schizophrenia do not inevitably develop schizophrenia; other factors (e.g., environment) must be involved in determining a schizophrenia outcome. If a vulnerability–liability model of

schizophrenia is correct in its postulation of an environmental influence, then other biologic or psychosocial environmental factors may prevent or cause schizophrenia in genetically vulnerable individuals.

Some data indicate that the age of the father correlates with the development of schizophrenia. In studies of schizophrenia patients with no history of illness in either the maternal or paternal line, those born from fathers older than the age of 60 years were vulnerable to developing the disorder. Presumably, spermatogenesis in older men is subject to more significant epigenetic damage than in younger men.

Genetic Studies. The modes of genetic transmission in schizophrenia are unknown, but many genes are associated with schizophrenia. Newer studies using more direct methods, such as comparative genomic hybridization, small nucleotide polymorphism (SNP) chips, next generation sequencing (NGS), GWAS, and the Clustered Regularly Interspaced Short Palindromic Repeats-associated Nuclease 9 (CRISPR/Cas9) genomic editing have revolutionized the genetic research of schizophrenia, and the number of genes associated with schizophrenia continues to rise. Many of these are likely chance findings. However, at least some are plausible candidates for contributing to schizophrenia vulnerability.

Linkage and association genetic studies have provided strong evidence for several specific candidate genes. The best candidates are those involved in synaptic transmission, including those for various monoamine receptors and those involved in glutamate release and signaling.

Given the role dopamine plays in schizophrenia, it is no surprise that many genetic studies have concentrated on genes involved in dopamine regulation. For example, some studies implicate catecholamine O-methyltransferase (COMT) polymorphism, which is involved in dopamine metabolism (as well as other catecholamines).

Copy number variation (CNV) studies suggest that perhaps between 2 to 5 percent of schizophrenia may be due, in part, to genetic variants that are highly penetrant but very rare. These included genes that were involved in regulating synaptic function and neurodevelopment. An example of a rare variant that is associated with psychosis is the 22q11.2 microdeletion, which causes 22q11.2 deletion or velocardiofacial syndrome (also called DiGeorge syndrome), which occurs in about 1 in 4,000 live births.

However, most of the risk is explained by common alleles, numbering in the hundreds, each having a small effect on risk. GWAS studies have yielded several loci of interest, including the DRD genes which encode the dopamine receptors, as well as several other loci involved in functions thought essential to the pathogenesis of schizophrenia. These include genes involved with glutamate, calcium signaling, dendritic spine formation, and other aspects of neuronal and neurodevelopmental function. As will be described in greater detail below, subsequent research has focused on genes related to the immune system and involved in synaptic pruning.

Many implicated genes do not code for proteins such as those described above, but have a role in genetic processing, affecting transcription and various epigenetic factors.

The extensive and sometimes conflicting findings are likely related to the heterogeneity of the disorder, and researchers are working to develop endophenotypes that more closely map to the genetics of the disorder. For example, prepulse inhibition is a likely candidate for a schizophrenia endotype. Researchers have identified several other endophenotype traits. These have the benefit of being measurable and lend themselves to quantitative analysis.

THE PSYCHOLOGY OF THE DISORDER

Family Dynamics

In a classic early study of 4-year old British children, children rated as having a poor mother–child relationship had a six-fold increase in the risk for schizophrenia. However, this leaves open the question of which came first, the poor relationship or the child's disease-related inability to form close relationships. It is telling that those who were adopted away from their mothers were more likely to develop schizophrenia if raised in adverse circumstances. In another study, children of schizophrenic mothers raised in a kibbutz (a type of commune) were more likely to develop schizophrenia than children raised in a family home. Nevertheless, no well-controlled evidence indicates that a specific family pattern plays a causative role in the development of schizophrenia. Some patients with schizophrenia do come from dysfunctional families, just as do many nonpsychiatrically ill persons. It

is crucial, however, not to overlook pathologic family behavior that can significantly increase the emotional stress with which a vulnerable patient with schizophrenia must cope.

ETIOLOGY

Biologic Theories

The Dopamine Hypothesis. The simplest formulation of the dopamine hypothesis of schizophrenia posits that schizophrenia results from too much dopaminergic activity. The theory evolved from two observations. First, the efficacy and the potency of many antipsychotic drugs (i.e., the dopamine receptor antagonists [DRAs]) correlate with their ability to act as antagonists of the dopamine type 2 (D_2) receptor. Second, drugs that increase dopaminergic activity, notably cocaine and amphetamine, are psychotomimetic. There is also support from the fact that certain functions that are regulated by dopamine (e.g., prepulse inhibition) are abnormal in patients with schizophrenia.

The basic theory does not comment on whether dopaminergic hyperactivity results from too much dopamine, too many dopamine receptors, hypersensitivity of the receptors to dopamine, or a combination of these.

Which dopamine tracts in the brain are involved is also not specified. Historically, models of schizophrenia suggested that dysfunctions in the mesolimbic pathway were responsible for the positive symptoms of schizophrenia. This was due to a variety of observations, including that seizures and tumors in these regions produced schizophrenia-like symptoms. Also, amphetamines, which can induce psychosis, seemed to affect the nucleus accumbens, and antipsychotics injected in this area seemed to reverse this effect.

However, subsequent research suggests that the striatum (usually thought to be involved in motor function) plays an important role. This is suggested by functional neuroimaging studies, which found that the most significant differences in dopamine function found for schizophrenic patients were in the dorsal striatum and associated projections. This relation is also true for people at high risk for schizophrenia. This area has an integrative role, and

dysfunctions in this area could explain the associative deficits that occur in schizophrenia. Also, as this area has a vital role in habit formation, it may argue for a model of psychosis as a habitual or rigid type of thinking, in which a person has difficulty considering alternative explanations for an experience.

Serotonin. Current hypotheses posit serotonin excess as a cause of both positive and negative symptoms in schizophrenia. The robust serotonin antagonist activity of clozapine and other second-generation antipsychotics coupled with the effectiveness of clozapine to decrease positive symptoms in chronic patients has contributed to the validity of this proposition.

GABA. Some have implicated the inhibitory amino acid neurotransmitter γ-aminobutyric acid (GABA) in the pathophysiology of schizophrenia based on the finding that some patients with schizophrenia have a loss of GABAergic neurons in the hippocampus. GABA has a regulatory effect on dopamine activity, and the loss of inhibitory GABAergic neurons could lead to the hyperactivity of dopaminergic neurons.

Neuropeptides. Neuropeptides, such as substance P and neurotensin, are localized with the catecholamine and indoleamine neurotransmitters and influence the action of these neurotransmitters. Alteration in neuropeptide mechanisms could facilitate, inhibit, or otherwise alter the pattern of firing in these neuronal systems.

Glutamate. Glutamate is also of interest, as ingestion of phencyclidine, a glutamate antagonist, produces an acute syndrome similar to schizophrenia. The hypotheses proposed about glutamate include those of hyperactivity, hypoactivity, and glutamate-induced neurotoxicity.

Acetylcholine and Nicotine. As noted, some studies suggest deficits in muscarinic and nicotinic receptors. These receptors play a role in the regulation of neurotransmitter systems involved in cognition, which is impaired in schizophrenia.

Neural Circuits (The Disconnect Hypothesis). There has been a gradual evolution from conceptualizing schizophrenia as a disorder that

involves discrete areas of the brain to a perspective that views schizophrenia as a disorder of brain neural circuits. For example, as mentioned previously, the basal ganglia and cerebellum are reciprocally connected to the frontal lobes, and the abnormalities in frontal lobe function seen in some brain imaging studies may be due to disease in either area rather than in the frontal lobes themselves. It is possible that an early developmental lesion of the dopaminergic tracts to the prefrontal cortex results in the disturbance of the prefrontal and limbic system function and leads to the positive and negative symptoms and cognitive impairments observed in patients with schizophrenia.

Of particular interest in the context of neural circuit hypotheses linking the prefrontal cortex and limbic system are studies demonstrating a relationship between hippocampal morphologic abnormalities and disturbances in prefrontal cortex metabolism or function (or both). Data from functional and structural imaging studies in humans suggest that whereas dysfunction of the anterior cingulate basal ganglia thalamocortical circuit underlies the production of positive psychotic symptoms, dysfunction of the dorsolateral prefrontal circuit underlies the production of primary, enduring negative or deficit symptoms. There is a neural basis for cognitive functions that are impaired in patients with schizophrenia. The observation of the relationship among impaired working memory performance, disrupted prefrontal neuronal integrity, altered prefrontal, cingulate, and inferior parietal cortex, and altered hippocampal blood flow provides strong support for disruption of the normal working memory neural circuit in patients with schizophrenia. The involvement of this circuit, at least for auditory hallucinations, has been documented in several functional imaging studies that contrast hallucinating and nonhallucinating patients.

Viruses, Neurotoxicity, and Neuroinflammation. Most carefully conducted investigations that have searched for evidence of neurotoxic viral infections in schizophrenia have had negative results. However, as noted, indirect epidemiologic data support a viral role. Nonetheless, the inability to detect genetic evidence of viral infection reduces the significance of all circumstantial data. The possibility of autoimmune brain antibodies has some data to support it; the pathophysiologic process, if it exists, however, probably explains only a subset of the population with schizophrenia.

The neurotoxicity hypothesis suggests that psychosis can be toxic, increasing stress levels and associated cortisol, leading to brain changes. Also, the use of exogenous toxins such as cannabis and alcohol may further contribute. There is also some evidence that antipsychotic medications could contribute as well. As described below, however, the lack of evidence for neurodegeneration argues against this process.

Many studies have suggested that neuroinflammation plays a role in the pathogenesis of schizophrenia. Schizophrenia and certain autoimmune diseases have overlapping clinical, epidemiologic, and genetic features. Furthermore, at least a subset of patients with schizophrenia has laboratory findings indicating immune activation. These findings may be particularly prominent in patients with structural brain changes, although these results are inconsistent.

Several GWAS studies have found implicated genes that regulate the immune response, particularly the major histocompatibility complex (MHC) region and specific genes involved in synaptic pruning, lending more support for the neurodevelopmental hypothesis, discussed next.

Increasing Evidence Suggests that Schizophrenia Is a Neurodevelopmental Disorder. Schizophrenia is likely a disorder of neurodevelopment, in which the standard neural structure does not develop properly. Earlier researchers speculated that this would be the case based on the observation that many patients who developed schizophrenia in early adulthood had motor and cognitive impairments as younger persons. Also, as discussed above, obstetrical complications are a risk factor for schizophrenia. Furthermore, for many patients with schizophrenia, cognitive deficits do not deteriorate significantly after illness onset. Evidence for this includes the lack of gliosis found in the brains of schizophrenia patients, as well as no consistent evidence of neurodegeneration, which suggests that the significant deficits are not due to cell death but rather the lack of proper cell growth. Also, many of the genes implicated in schizophrenia have relatively higher expression before birth and are likely involved in early brain development. Some of the genes may even affect the placenta, making it more sensitive to environmental stress.

As noted, one of the strongest genetic associations found to date for schizophrenia has been with variations in the MHC. These genes, particularly

the C4 alleles, are involved in synaptic pruning during critical developmental periods, which occur during adolescence and adulthood, and may explain why symptoms of schizophrenia only become apparent during this period.

Schizophrenia Likely Involves Multiple Dysfunctions at Various Levels. We know from neurologic patients suffering various focal lesions that the lesions causing hallucinations are often in the networks associated with that sensory system; thus, visual hallucinations are associated with occipital lesions as well as other areas along the visual pathway, such as the striatum and thalamus. Similarly, auditory hallucinations can be caused by lesions in the auditory cortex, hippocampus, amygdala, or thalamus. However, most patients with these focal lesions retain insight and recognize their hallucinations for what they are. Lesions in the corticostriatal networks can cause loss of insight, and the dopamine-related dysfunctions in this network likely account for the delusional beliefs about the hallucinations and other disordered thoughts. Still, other circuits are involved in the affective reaction to these abnormal experiences. In this way, the symptoms of schizophrenia are probably due to multiple dysfunctions along several networks.

This approach to understanding schizophrenia helps account for why antipsychotics are only partly useful for treating schizophrenia. By normalizing the dopamine dysfunction, antipsychotics decrease the abnormally high dopamine signaling in the associative striatum, and reduce the psychotic symptoms associated with the disorder. However, they are acting only on this particular circuit, and therefore have little effect on the negative and cognitive symptoms of the disorder.

Psychosocial Theories

If schizophrenia is a disease of the brain, it is likely to parallel diseases of other organs (e.g., myocardial infarctions, diabetes) whose courses are affected by psychosocial stress. Thus, clinicians should consider both psychosocial and biologic factors affecting schizophrenia.

The disorder affects individual patients, each of whom has a unique psychological makeup. Although many psychodynamic theories about the pathogenesis of schizophrenia seem outdated, perceptive clinical

observations can help contemporary clinicians understand how the disease may affect a patient's psyche.

Psychoanalytic Theories. Sigmund Freud thought that schizophrenia resulted from developmental fixations early in life. These fixations produce defects in ego development, and he postulated that such defects contributed to the symptoms of schizophrenia. Margaret Mahler and Paul Federn concentrated on distortions in the mother–infant relationship, and Harry Stack Sullivan viewed schizophrenia as a disturbance in interpersonal relatedness. To Sullivan, schizophrenia is an adaptive method used to avoid panic, terror, and disintegration of the sense of self. The source of pathologic anxiety results from cumulative experiential traumas during development.

THE OBJECT RELATIONS DEFICIT MODEL OF SCHIZOPHRENIA. Object relationship theory posits that relations with other people are "introjected" and applied to new relationships. One can approach the challenge of new relationships by drawing on the internal models one collects from past relationships. In the case of schizophrenia, this normal process is disrupted, presumably due to errors in neurodevelopment that affect the filters that interpret information from the environment. Thus, the introjects one collects are distorted and incomplete, and interpreted as dangerous and threatening. As a result, the patient avoids relationships, thus having less chance for corrective experiences. Reality becomes terrifying, and the reaction is to create an alternate reality through psychotic thinking.

This theory has the benefit of accounting for both the positive and negative symptoms of schizophrenia. It also points at potential treatments. For example, the job of the therapist is to provide positive experiences that the patient can introject to help correct their distorted world view.

Regardless of the theoretical model, all psychodynamic approaches rely on the premise that psychotic symptoms have meaning in schizophrenia. Patients, for example, may become grandiose after an injury to their self-esteem. Similarly, all theories recognize that human relatedness may be terrifying for persons with schizophrenia. Although research on the efficacy of psychotherapy with schizophrenia shows mixed results, concerned persons who offer compassion and a sanctuary in the confusing world of schizophrenia must be a cornerstone of any overall treatment plan. Long-term

follow-up studies show that some patients who bury psychotic episodes do not benefit from exploratory psychotherapy, but those who can integrate the psychotic experience into their lives may benefit from some insight-oriented approaches. There is renewed interest in the use of long-term individual psychotherapy in the treatment of schizophrenia, especially when combined with medication.

Learning Theories. According to learning theorists, children who later have schizophrenia learn irrational reactions and ways of thinking by imitating parents who have significant emotional problems. In learning theory, the poor interpersonal relationships of persons with schizophrenia develop because of poor models for learning during childhood.

Bipolar Disorders

The bipolar disorders include bipolar disorder type I, commonly referred to as manic depression, bipolar type II disorder, and cyclothymia. Historically, we considered these mood disorders to be on a continuum with depressive disorders—hence the concept of polarity, with depression at one end and mania the other. Since the 1980s and the introduction of DSM-III, we separated the bipolar disorders from depressive disorders mainly because the disorders have different epidemiologic characteristics, courses, and treatments. However, at various times experts in mood disorders have reconsidered this separation, noting that many patients with major depressive disorder have past episodes of at least some manic symptoms. Many authorities see considerable continuity between recurrent depressive and bipolar disorders. There continues to be widespread discussion and debate about the bipolar spectrum, which incorporates classic bipolar disorder, bipolar II, and recurrent depressions.

THE CLINICAL PRESENTATION

Manic Episodes

Manic patients are excited, talkative, sometimes amusing, and frequently hyperactive. Their speech is usually rapid and loud and challenging to interrupt. It is commonly referred to as *pressured*, appearing as if driven by some unknown urgency. Pressured speech is considered a hallmark of mania.

An elevated, expansive, or irritable mood is the hallmark of a manic episode. The elevated mood is euphoric and often infectious and can even cause a countertransferential denial of illness by an inexperienced clinician. Although uninvolved persons may not recognize the unusual nature of a

patient's mood, those who know the patient recognize it as abnormal. Alternatively, the mood may be irritable, especially when someone prevents a patient from some unrealistic plan. Patients often exhibit a change of predominant mood from euphoria early in the course of the illness to later irritability. They also have a low frustration tolerance, which can lead to feelings of anger and hostility. Manic patients may be emotionally labile, switching from laughter to irritability to depression in minutes or hours.

Manic patients describe rapid thoughts, as inferred from their speech. As the manic state increases, their speech contains puns, jokes, rhymes, or plays on words. They may seem clever, even brilliant. Manic patients are often easily distracted, and their cognitive functioning in the manic state is unrestrained, with an accelerated flow of ideas. At a still higher activity level, associations become loosened, the ability to concentrate fades, and flight of ideas, clanging, and neologisms appear. In acute manic excitement, speech can be incoherent and indistinguishable from that of a person with schizophrenia.

The manic patient's thought content includes themes of self-confidence and self-aggrandizement.

At times, manic patients are grossly psychotic and disorganized and require physical restraints and the intramuscular injection of sedating drugs.

A 37-year-old engineer had experienced three manic episodes for which he had been hospitalized; all three episodes were preceded by several weeks of moderate psychomotor retardation. Although he had responded to lithium each time, once outside the hospital, he had been reluctant to take it and eventually refused to do so. Now that he was "euthymic," after his third and most disruptive episode during which he had badly beaten his wife, he could more accurately explain how he felt when manic. He experienced mania as "God implanted in him," so he could serve as "testimony to man's communication with God." He elaborated as follows: "Ordinary mortals will never, never understand the supreme manic state which I'm privileged to experience every few years. It is so vivid, so intense, so compelling. When I feel that way, there can be no other explanation: To be manic is, ultimately, to be God. God himself must be supermanic: I can feel it when mania enters through my left brain

like laser beams, transforming my sluggish thoughts, recharging them, galvanizing them. My thoughts acquire such momentum, they rush out of my head, to disseminate knowledge about the true nature of mania to psychiatrists and all other ordinary mortals. That's why I will never accept lithium again—to do so is to obstruct the divinity in me." Although he was on the brink of divorce, he would not yield to his wife's plea to go back on lithium.

Delusions occur in 75 percent of all manic patients. Mood-congruent manic delusions are often concerned with great wealth, extraordinary abilities, or power. Bizarre and mood-incongruent delusions and hallucinations also appear in mania.

A 29-year-old female college graduate, mother of two children, and wife of a bank president, had experienced several manic and retarded depressive episodes that had responded to lithium carbonate. She was referred because she had developed the delusion that she had been involved in an international plot. Careful probing revealed that the delusion represented further elaboration, in a rather fantastic fashion, of a grandiose delusion that she had experienced during her last postpartum manic episode. She believed that she had played an important role in uncovering the plot, thereby becoming a national hero. Nobody knew about it, she contended, because the circumstances of the plot were top secret. She further believed that she had saved her country from the international scheme and suspected that she was singled out for persecution by the perpetrators of the plot. At one point, she had even entertained the idea that the plotters sent special radio communications to intercept and to interrupt her thoughts. As is typical in such cases, she was on a heavy dosage of a lithium–antipsychotic combination. The consultation was requested because the primary mood symptoms were under control, yet, she had not given up her grandiose delusion. She flippantly remarked, "I must be crazy to believe in my involvement in an international plot," but she could not help but believe in it. Over several months, seen typically in 60-minute sessions weekly, the patient had developed sufficient trust that the psychiatrist could gently challenge her

beliefs.

She was, in effect, told that her self-professed role in the international scheme was highly implausible and that someone with her superior education and high social standing could not entertain a belief, to use her own words, "as crazy as that." She eventually broke into tears, saying that everyone in her family was so accomplished and famous that to keep up with them she had to be involved in something grand; in effect, the international scheme, she said, was her only claim to fame: "Nobody ever gives me credit for raising two kids, and throwing parties for my husband's business colleagues: My mother is a dean, my older brother holds high political office; my sister is a medical researcher with five discoveries to her credit [all true], and who am I? Nothing. Now, do you understand why I need to be a national hero?" As she alternated, over subsequent months, between such momentary flashes of insight and delusional denial, antipsychotic medication was gradually discontinued. Maintained on lithium, she now only makes passing reference to the grand scheme. She was encouraged to pursue her career goal toward a master's degree in library science. (Courtesy of HS Akiskal, M.D.)

Grossly, orientation and memory are intact, although some manic patients may be so euphoric that they answer questions testing orientation incorrectly. Emil Kraepelin called the symptom delirious mania.

We know less about the cognitive deficits associated with bipolar disorder than such chronic disorders like schizophrenia. However, there is some evidence to suggest they share some common deficits.

Impaired judgment is a hallmark of manic patients. They may break laws about credit cards, sexual activities, and finances and sometimes involve their families in financial ruin. Manic patients also have little insight into their disorder. Their disinhibition may result in other examples of poor judgment, such as making phone calls during inappropriate times of the day. Pathologic gambling, a tendency to disrobe in public places, wearing clothing and jewelry of bright colors in unusual or outlandish combinations, and inattention to small details (e.g., forgetting to hang up the telephone) are also symptomatic of the disorder. Patients act impulsively, and at the same time, with a sense of conviction and purpose. They are sometimes preoccupied

with religious, political, financial, sexual, or persecutory ideas that can evolve into complex delusional systems. Occasionally, manic patients become regressed and play with their urine and feces.

About 75 percent of all manic patients are assaultive or threatening at some time. Manic patients are at increased risk for suicide. However, the most significant risk seems to be when bipolar patients are depressed. Manic patients often drink alcohol excessively, perhaps in an attempt to self-medicate.

Depressive Episodes

The depressive episodes in bipolar disorder are similar to those described for depressive disorders. Many experts in the field feel that there are qualitative differences in the depressive episodes experienced by bipolar patients, and researchers have attempted to find reliable differences between bipolar I disorder depressive episodes and episodes of major depressive disorder, but the differences are elusive. Although the data are inconsistent and controversial, some clinicians report that the depressed patients who we later diagnose as having bipolar disorder often have hypersomnia, psychomotor retardation, psychotic symptoms, a history of postpartum episodes, a family history of bipolar I disorder, and a history of antidepressant-induced hypomania. Table 6-1 lists some differences between the depressive disorder seen in bipolar disorder and major depression.

Table 6-1
Differentiating Characteristics of Bipolar and Unipolar Depressions

	Bipolar	Unipolar
History of mania or hypomania (definitional)	Yes	No
Temperament and personality	Cyclothymic and extroverted	Dysthymic and introverted
Sex ratio	Equal	More women than men

Age of onset	Teens, 20s, and 30s	30s, 40s, and 50s
Postpartum episodes	More common	Less common
Onset of episode	Often abrupt	More insidious
Number of episodes	Numerous	Fewer
Duration of episode	3–6 mo	3–12 mo
Psychomotor activity	Retardation > agitation	Agitation > retardation
Sleep	Hypersomnia > insomnia	Insomnia > hypersomnia
Family History		
Bipolar disorder	Yes	±
Unipolar disorder	Yes	Yes
Alcoholism	Yes	Yes
Pharmacologic Response		
Most antidepressants	Induce hypomania–mania	±
Lithium carbonate	Prophylaxis	±

Bipolar Disorder in Children and Adolescents

It is easy to misdiagnose mania in adolescents as a conduct disorder, antisocial personality disorder, or schizophrenia. Symptoms of mania in adolescents may include psychosis, alcohol or other substance abuse, suicide attempts, academic problems, philosophical brooding, OCD symptoms, multiple somatic complaints, marked irritability resulting in fights, and other antisocial behaviors. Although we can see many of these symptoms in healthy adolescents, severe or persistent symptoms should cause clinicians to consider bipolar I disorder in the differential diagnosis.

DIAGNOSIS

Patients with both manic and depressive episodes or patients with manic episodes alone are said to have *bipolar disorder*. The terms unipolar mania and pure mania are sometimes used for patients who are bipolar but who do not have depressive episodes.

Three additional categories of mood disorders are hypomania, cyclothymia, and dysthymia. Hypomania is an episode of manic symptoms that do not meet the criteria for a manic episode. Cyclothymia and dysthymia are disorders that represent less severe forms of bipolar disorder and major depression, respectively.

Bipolar I Disorder

Bipolar I patients have at least one manic episode. It is what most people mean when they refer to bipolar as a disorder. Table 6-2 compares the different approaches to diagnosing bipolar I disorder.

Table 6-2
Bipolar I Disorder

Bipolar I Disorder		
	DSM-5	**ICD-10**
Name	Bipolar I Disorder	Bipolar Affective Disorder *NOTE:* ICD-10 does not distinguish between Bipolar I and II, requiring only history of discrete episodes of mania, hypomania and/or depression, with episodes demarcated by switches in mood/affect.
Duration	• Manic episode: 1 wk+	

	• Hypomanic episode: 4 days+ • Major depressive episode: 2 wk+	
Symptoms	**Manic or hypomanic episodes** • Abnormally ↑ or irritable mood (required) • Grandiose thoughts • ↓ Need for sleep • Pressured speech • Racing and expansive thoughts • Distractibility • Hyperactivity • Impulsivity/high-risk activities **Depressive episodes** • Similar to that for major depressive disorder	• History of episodes of mania, hypomania and/or depression • Switches in mood/affect **Mania** • Abnormally ↑ or irritable mood (required) • ↑ Activity • ↑ Talkativeness • Flight of ideas/racing thoughts • Social disinhibition • ↓ Need for sleep • Grandiose thoughts • Distractibility • Impulsivity/recklessness • Hypersexuality **Hypomania** • Abnormally ↑ mood (required) • Psychomotor agitation • ↑ Talkativeness • Poor concentration/distractibility • ↓ Need for sleep • Hypersexuality • Impulsivity or ↑ spending • Over-familiarity **Depressive episode**

- Depressed mood
- Loss of interest or pleasure
- Decreased energy

Additional symptoms:
- Low self-esteem
- Excessive guilt or shame
- Recurrent thoughts of death or suicide
- Poor concentration
- Psychomotor changes
- Sleep disturbance
- Change in appetite and/or weight

| Required number of symptoms | At least 1 manic episode
• Abnormally ↑ or irritable mood (required)
≥3 of the other symptoms (4 if irritable mood) | **Bipolar affective disorder, current episode hypomanic**
• Hypomania
• History of a prior affective episode (manic, hypomanic, depressed, mixed)
Bipolar affective disorder, current episode manic
• Mania
• History of prior affective episode (manic, hypomanic, depressed, mixed)
Bipolar disorder, current episode mild/moderate/severe depression
• Depressive episode
• History of prior affective |

		episode (manic, hypomanic, depressed, mixed) **Bipolar disorder, current episode mixed** • Mixture or rapid alternation of hypomanic, manic and/or depressive symptoms • History of prior affective episode (manic, hypomanic, depressed, mixed)
Exclusions (not better explained by):	Drug abuse Medication effect Other medical condition Other psychiatric illness	Psychoactive substance use Another mental disorder
Psychosocial Impact	**Manic episode:** impaired functioning or needing hospitalization **Hypomanic episode:** No impairment or need for hospitalization **Depressive episode:** marked distress and/or psychosocial	

Symptom Specifiers		
	impairment	
Symptom Specifiers	**With mixed features:** • Either depressive or manic/hypomanic episode • Additional symptoms of depressive or manic/hypomanic period (not full criteria) **With rapid cycling:** • ≥4 mood episodes in 1 yr • ≥2-mo period of partial/full remission between episodes **With melancholic features:** Similar to that for major depressive disorder **With atypical features:** Similar to that for major depressive disorder **With anxious distress:** ≥2 symptoms among the	**Current episode hypomanic** **Current episode manic without psychotic symptoms** **Current episode manic with psychotic symptoms** **mood congruent** **mood incongruent** **Current episode of depression** **Current episode mixed** **Currently in remission**—no symptoms. History of previous episodes.

following:

- Feeling tense
- Restlessness
- Difficulty with concentration due to worrying
- ↑ fear without cause
- Fear of loss of control

With mood-congruent psychotic features

With mood-incongruent psychotic features

With catatonia

| Severity Specifiers | **Mild**—minimal symptoms, no to minimal impairment and/or distress **Moderate** —moderate symptomatology and impairment **Severe**—maximal symptoms, marked distress and impairment | **For current episode of depression** **Mild:** 2–3 symptoms **Moderate:** ≥4 symptoms, including ≥2 among loss of pleasure, depressed mood, and low energy **Severe:** symptoms are marked and distressing, suicidal thoughts are common **without psychotic symptoms** **with psychotic** |

		symptoms mood congruent mood incongruent
Course Specifiers	**With peripartum onset:** • Episode occurs during pregnancy or within 4 wk after delivery **With seasonal pattern** • Pattern present for ≥2 yr **In partial remission** **In full remission**	

Patients with this disorder may have a single or recurrent episode. We consider manic episodes as distinct when they are separated by at least 2 months without significant symptoms of mania or hypomania. The episodes should not be due to another apparent cause, such as medication (including an antidepressant).

Bipolar II Disorder

Bipolar patients have hypomania rather than mania—manic-type symptoms that are not as severe or as impairing as full mania. Table 6-3 compares the different approaches to diagnosing bipolar II disorder.

It is easy to confuse other disorders, including dramatic but normal moods, with hypomania. For example, some patients with depression may be thrilled and very euphoric once emerging from a depressive episode. Many medications, including antidepressants, can induce hypomanic symptoms. The diagnostic approaches attempt to help distinguish hypomania from these other causes of a heightened mood.

Diagnostic Specifiers

Rapid Cycling. Some patients experience frequent manic episodes. When a patient has at least four such episodes in a year, we diagnose them with the rapid cycling subtype of bipolar I disorder. Patients with rapid cycling bipolar I disorder are likely to be female and to have had depressive and hypomanic episodes. No data indicate that rapid cycling has a familial pattern of inheritance; thus, an external factor such as stress or drug treatment may provoke rapid cycling.

**Table 6-3
Bipolar II Disorder**

Bipolar II Disorder		
	DSM-5	**ICD-10**
Name	Bipolar II Disorder	Bipolar Affective Disorder *NOTE:* ICD-10 does not distinguish between Bipolar I and II, requiring only history of discrete episodes of mania, hypomania and/or depression, with episodes demarcated by switches in mood/affect.
Duration	See Table 6-2 for hypomanic and depressive episodes	See Table 6-2
Symptoms	**Hypomanic episodes** (see Table 6-2) **Depressive episodes** (see Table 6-2)	See Table 6-2

Required number of symptoms	≥1 hypomanic episode ≥1 depressive episode	
Exclusions (not better explained by):	Drug abuse Medication effect Other medical condition Another psychiatric illness Diagnose bipolar I if h/o manic episode	Psychoactive substance use Better explained by another mental disorder
Psychosocial Impact	• Hypomanic episode: NO marked impairment in functioning and NO hospitalization necessitated • Depressive episode: marked distress and/or impairment in psychosocial functioning	
Symptom Specifiers	**Current episode (see Table 6-2 for definitions)** **Depressed** **Hypomanic** **With anxious distress**	See Table 6-2

	With mixed features	
	With rapid cycling	
	With melancholic features	
	With atypical features	
	With mood-congruent psychotic features	
	With mood-incongruent psychotic features	
	With catatonia	
Severity Specifiers	**Mild**—minimal symptoms, no to minimal impairment and/or distress	See Table 6-2
	Moderate—moderate symptomatology and impairment	
	Severe—maximal symptoms, marked distress and impairment	
	(note, impairment occurs during depressive episode)	
Course	**With peripartum**	

Specifiers	onset—see Table 6-2
	With seasonal pattern—see Table 6-2
	In partial remission
	In full remission

With Seasonal Pattern. As with depressive disorders, mania can occur primarily during certain seasons. Some studies have found a higher prevalence of manic episodes in the spring and summer months. However, available research is most convincing for the seasonality of depressive episodes.

With Peripartum Onset. Mania occurring after pregnancy is a critical issue given the potential risk to the child.

Catatonia. Clinicians often do not associate catatonic symptoms with bipolar I disorder because of the marked contrast between the symptoms of stuporous catatonia and the classic symptoms of mania. They are associated with depressive episodes, however.

Other Bipolar Disorders

Cyclothymia. Cyclothymic disorder has also been appreciated clinically for some time as a less severe form of bipolar disorder. Patients with cyclothymic disorder have at least 2 years of frequently occurring hypomanic symptoms that cannot fit the diagnosis of a manic episode and of depressive symptoms that cannot fit the diagnosis of a major depressive episode. Table 6-4 compares the different approaches to diagnosing cyclothymia.

**Table 6-4
Cyclothymic Disorder**

Cyclothymic Disorder		
	DSM-5	**ICD-10**
Name	Cyclothymic Disorder	Cyclothymia
Duration	≥2 yr (≥1 for children) with depressive and hypomanic symptoms present ≥50% of the time	2-yr w/ periods of depression and elevated mood, without ever meeting criteria for a depressive episode or manic episode
Symptoms	Hypomanic episodes (see Table 6-2) Depressive episodes (see Table 6-2)	Unstable moods, many periods of depression or mild elation which are insufficient to be called hypomania or mild major depressive disorder
Required number of symptoms	Symptoms of hypomania and depression present, without ever meeting full criteria for a depressive episode or manic episode	Several episodes, symptoms are insufficient for a diagnosis of hypomania, major depression or another bipolar affective disorder
Exclusions (not better explained	• Substance use • Medication effect	Bipolar affective disorder (though history of bipolar

by):	• Other medical condition • Other mental illness (i.e., Bipolar I or II)	affective disorder may be present)
Psychosocial Impact	Marked distress or impairment in areas of functioning	
Symptom Specifiers	**With anxious distress:** including at least two symptoms among feeling tense, restlessness, difficulty with concentration due to worrying, excessive fear without identifiable cause, fear of loss of control	Affective personality disorder Cycloid personality Cyclothymic personality

Mr. B, a 25-year-old single man, came for evaluation due to irritability, insomnia, jumpiness, and excessive energy. He reported that such episodes lasted from a few days to a few weeks and alternated with longer periods of feeling hopeless, dejected, and worn out with thoughts of suicide. Mr. B reported having been this way for as long as he could remember. He had never been treated for his symptoms. He denied using drugs and said he had "only the occasional drink to relax."

As a child, Mr. B went from one foster family to another and was an irresponsible and trouble-making child. He frequently ran away from home, was absent from school, and committed minor crimes. He ran away from his last foster family at the age of 16 years and drifted ever since, taking occasional odd jobs. When he became restless at one location or job, he quickly moved on to the next. He did not have close friends because he would form and end friendships quickly.

DIFFERENTIAL DIAGNOSIS

When a patient with bipolar I disorder has a depressive episode, the differential diagnosis is the same as that for a patient with major depressive disorder. However, when a patient is manic, there is a broad differential, including other mood disorders, psychiatric disorders, medical disorders, and substances. We list some of these in Table 6-5.

Psychotic Disorders

It can be tough to distinguish a manic episode from the acute psychosis of a patient experiencing a psychotic episode. Although challenging, a differential diagnosis is possible. Merriment, elation, and infectiousness of mood are much more common in manic episodes than in schizophrenia. The combination of a heightened mood, rapid speech, and hyperactivity weighs toward mania. Mania often begins rapidly and is a marked change from previous behavior. Family history is also helpful.

When evaluating patients with catatonia, clinicians should look carefully for a history of manic or depressive episodes and a family history of mood disorders. There is an unfortunate tendency to misdiagnose manic symptoms in persons from minority groups (mainly Black and Hispanic) as schizophrenic symptoms.

Personality Disorders

Hypomania can frequently be confused with the mood lability of personality disorders, particularly borderline personality disorder. Patients with a borderline personality disorder often have a severely disrupted life, similar to that of patients with bipolar II disorder, because of the multiple episodes of significant mood disorder symptoms.

    Schizoaffective disorder

A 19-year-old single woman presented with the chief complaint that "all men are bastards." Since her early teens, with the onset of her menses, she had complained of extreme variability in her moods on a nearly daily basis; irritability with hostile outbursts was her main affect, although more-protracted hypersomnic depressions with multiple overdoses and wrist slashings had led to at least three hospitalizations. She also had migrainous headaches that, according to her mother, had motivated at least one of those overdoses. Despite her tempestuous and suicidal moods that led to these hospitalizations, she complained of "inner emptiness and a bottomless void." She had used heroin, alcohol, and stimulants to overcome this troubling symptom. She also gave history of ice cream craving and frequent purging. She was talented in English and wrote much-acclaimed papers on the American confessional poet Anne Sexton. She said that she was mentally disturbed because of a series of stepfathers who had all forced "oral rape" on her when she was between 11 and 15 years of age. She subsequently gave herself sexually to any man that she met in bars, no longer knowing whether she was a "prostitute" or a "nice

little girl." On two occasions, she had inflicted cigarette burns inside her vagina "to feel something." She had also engaged in a "brief lesbian relationship" that ultimately left her "emptier" and guilt ridden; nonetheless, she now believed that she should burn in hell because she could not get rid of "obsessing" about the excitement of mutual cunnilingus with her much older female partner. The patient's mother, who owned an art gallery, had been married five times and gave a history of unmistakable hypomanic episodes; a maternal uncle had died from alcohol-induced cirrhosis. The patient's father, a prominent lawyer known for his "temper and wit," had committed suicide. The patient was given phenelzine, eventually raised to 75 mg/day, at which point the mother described her as "the sweet daughter she was before age 13." At her next premenstrual phase, the patient developed insomnia, ran away from home at night, started "dancing like a go-go girl, met an incredibly handsome man" of 45 years of age (a pornography shop owner), and had a clandestine marriage to him. After many dose adjustments, she is now maintained on a combination of lithium (900 mg/day) and divalproex 750 mg/day. The patient now attends college and has completed four semesters in art history. In addition to control of her irritable and suicidal moods, bulimic and migraine attacks have abated considerably. Her marriage has been annulled on the basis that she was not mentally competent at the time of the wedding. She is no longer promiscuous and now expresses fear of intimacy with men that she is attracted to. She is receiving individual psychotherapy for this problem.

Medical Conditions

In contrast to depressive symptoms, which are present in almost all psychiatric disorders, manic symptoms are more distinctive. However, a wide range of medical disorders and substances can cause manic symptoms. Antidepressant treatment can also be associated with the precipitation of mania in some patients.

COMORBIDITY

Whereas men more frequently present with substance use disorders, women

more frequently present with comorbid anxiety and eating disorders. In general, patients with bipolar disorder more frequently show comorbidity of substance use and anxiety disorders than do patients with unipolar major depression. In the Epidemiologic Catchment Area (ECA) study, the lifetime history of substance use disorders, panic disorder, and OCD was approximately twice as high among patients with bipolar I disorder (61 percent, 21 percent, and 21 percent, respectively) than in patients with unipolar major depression (27 percent, 10 percent, and 12 percent, respectively). Comorbid substance use disorders and anxiety disorders worsen the prognosis of the illness and markedly increase the risk of suicide.

Although cyclothymic disorder is sometimes diagnosed retrospectively in patients with bipolar I disorder, no identified personality traits are associated explicitly with bipolar I disorder.

COURSE

The natural history of bipolar I disorder is such that it is often useful to make a graph of a patient's disorder and to keep it up to date as the treatment progresses (Fig. 6-1).

Onset

About 5 to 10 percent of patients with an initial diagnosis of major depressive disorder have a manic episode 6 to 10 years after the first depressive episode. The mean age for this switch is 32 years, and it often occurs after two to four depressive episodes.

Bipolar I disorder most often starts with depression (75 percent of the time in women, 67 percent in men) and is a recurring disorder. Most patients experience both depressive and manic episodes, although 10 to 20 percent experience only manic episodes.

The incidence of bipolar I disorder in children and adolescents is about 1 percent, and the onset can be as early as age 8 years.

Manic symptoms are common in older persons, although the range of causes is broad and includes nonpsychiatric medical conditions, dementia, and delirium, as well as bipolar I disorder. The onset of true bipolar I disorder in older persons is relatively uncommon.

Duration

The manic episodes typically have a rapid onset (hours or days) but may evolve over a few weeks. An untreated manic episode lasts about 3 months; therefore, clinicians should not discontinue giving drugs before that time. Depressive episodes are generally similar to those for depressive disorders.

Of persons who have a single manic episode, 90 percent are likely to have another. As the disorder progresses, the time between episodes often decreases. After about five episodes, however, the interepisode interval often stabilizes at 6 to 9 months. Of persons with bipolar disorder, 5 to 15 percent have four or more episodes per year and are classified as rapid cyclers.

Bipolar II Disorder

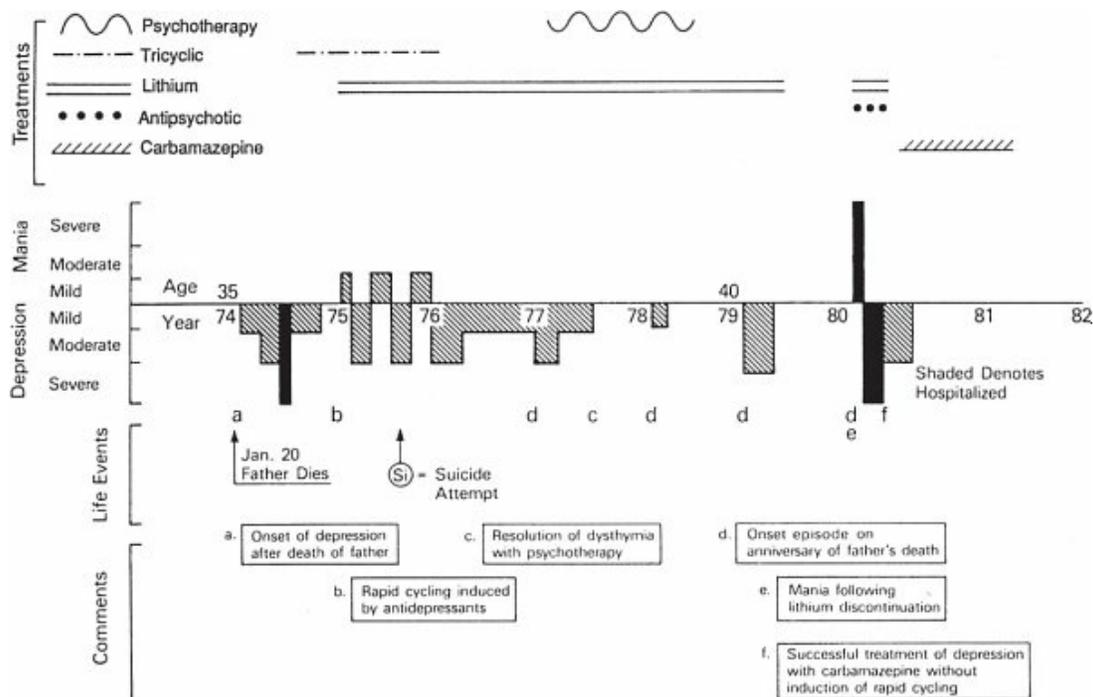
The course and prognosis of bipolar II disorder indicate that the diagnosis is stable because there is a high likelihood that patients with bipolar II disorder will have the same diagnosis up to 5 years later. Bipolar II disorder is a chronic disease that warrants long-term treatment strategies.


FIGURE 6-1
Graphing the course of a mood disorder. Prototype of a life chart. (Courtesy of Robert M. Post, M.D.)

PROGNOSIS

Patients with bipolar I disorder have a poorer prognosis than do patients with major depressive disorder. About 40 to 50 percent of patients with bipolar I disorder may have a second manic episode within 2 years of the first episode. Although lithium prophylaxis improves the course and prognosis of bipolar I disorder, probably only 50 to 60 percent of patients achieve significant control of their symptoms with lithium. About 7 percent of patients with bipolar I disorder do not have a recurrence of symptoms; 45 percent have more than one episode, and 40 percent have a chronic disorder. Patients may have from 2 to 30 manic episodes, although the mean number is about 9. About 40 percent of all patients have more than 10 episodes. On long-term follow-up, 15 percent of all patients with bipolar I disorder are well, 45 percent are well but have multiple relapses, 30 percent are in partial remission, and 10 percent are chronically ill. One-third of all patients with bipolar I disorder have chronic symptoms and evidence of significant social decline.

Prognostic Indicators

One 4-year follow-up study of patients with bipolar I disorder found that a premorbid poor occupational status, alcohol dependence, psychotic features, depressive features, interepisode depressive features, and male gender were all factors that contributed to a poor prognosis. A short duration of manic episodes, advanced age of onset, few suicidal thoughts, and few coexisting psychiatric or medical problems predict a better outcome.

TREATMENT APPROACH

Hospitalization

It is best to treat patients with severe mania in the hospital where aggressive dosing is possible, and it is possible to achieve an adequate response relatively quickly. Manic patients may test the limits of ward rules, shift responsibility for their acts onto others, or exploit the weaknesses of others, and they can create conflicts among staff members.

Choosing a Treatment

Medications are the treatments of choice for patients with bipolar disorders. However, psychotherapies can offer an essential adjunct to treatment.

Somatic Treatments

Pharmacotherapy

GENERAL CLINICAL GUIDELINES. We can divide the pharmacologic treatment of bipolar disorders into acute and maintenance phases. Bipolar treatment, however, also involves the formulation of different strategies for the patient who is experiencing mania or hypomania or depression. Lithium and its augmentation by antidepressants, antipsychotics, and benzodiazepines have been the principal approach to the illness. However, three anticonvulsant mood stabilizers—carbamazepine, valproate, and lamotrigine—are commonly used options, as well as a series of atypical antipsychotics. Often, it is necessary to try different medications before finding an optimal treatment. Furthermore, although one strives for monotherapy, in the case of bipolar disorder, polypharmacy is common.

Table 6-6
Recommendations for Pharmacologic Treatment of Acute Mania

First line	Monotherapy: lithium, divalproex, divalproex ER, olanzapine, risperidone, quetiapine, quetiapine XR, aripiprazole, ziprasidone, asenapine, paliperidone ER, cariprazine
	Adjunctive therapy with lithium or divalproex: risperidone, quetiapine, olanzapine, aripiprazole, asenapine
Second line	Monotherapy: carbamazepine, carbamazepine ER, ECT, haloperidol
	Combination therapy: lithium + divalproex
Third line	Monotherapy: chlorpromazine, clozapine, tamoxifen

	Combination therapy: lithium or divalproex + haloperidol, lithium + carbamazepine, adjunctive tamoxifen
Not recommended	Monotherapy: gabapentin, topiramate, lamotrigine, verapamil, tiagabine
	Combination therapy: risperidone + carbamazepine, olanzapine + carbamazepine

ECT, electroconvulsive therapy; XR or ER, extended release.
Modified from CANMAT/ISBD Guidelines.

Table 6-6 lists some recommended medications for treating acute mania.

Adherence to treatment, however, is often a problem because patients with mania frequently lack insight into their illness and refuse to take medication. Because impaired judgment, impulsivity, and aggressiveness combine to put the patient or others at risk, we must medicate patients when we need to protect themselves and others from harm.

INITIAL MEDICATION SELECTION. Figure 6-2 diagrams a strategy for selecting and preparing a bipolar patient for pharmacotherapy.

Acute Mania. The treatment of acute mania, or hypomania, usually is the most straightforward phase to treat. We can use agents alone or in combination to bring the patient down from a high.

Lithium Carbonate. Lithium carbonate is considered the prototypical mood stabilizer. However, because the onset of antimanic action with lithium can be slow, we often supplement it in the early phases of treatment by atypical antipsychotics, mood-stabilizing anticonvulsants, or high-potency benzodiazepines. Therapeutic lithium levels are between 0.6 and 1.2 mEq/L. The acute use of lithium has been limited in recent years by its unpredictable efficacy, problematic side effects, and the need for frequent laboratory tests. The introduction of newer drugs with more favorable side effects, lower toxicity, and less need for frequent laboratory testing has resulted in a decline in lithium use. For many patients, however, its clinical benefits can be remarkable.

Anticonvulsants. Valproate (valproic acid or divalproex sodium) has surpassed lithium in use for acute mania. Unlike lithium, valproate is only indicated for acute mania, although most experts agree it also has prophylactic effects. Normal dose levels of valproic acid are 750 to 2,500 mg/day, achieving blood levels between 50 and 120 µg/mL. Rapid oral loading with 15 to 20 mg/kg of divalproex sodium from day 1 of treatment has been well tolerated and associated with a rapid onset of response. Some laboratory testing is required during valproate treatment.

Carbamazepine has been used worldwide for decades as a first-line treatment for acute mania. The FDA approved it for acute mania in the United States in 2004. Typical doses of carbamazepine to treat acute mania range between 600 and 1,800 mg/day associated with blood levels of between 4 and 12 µg/mL. The keto congener of carbamazepine, oxcarbazepine, is better tolerated than carbamazepine, but the data for its efficacy are conflicting. A Cochrane review concluded there is insufficient evidence for this medication in acute mania.

Antipsychotics. The FDA approved many of the atypical antipsychotics for use in bipolar disorder. We list them in Table 6-7. Compared with older agents, such as haloperidol and chlorpromazine, atypical antipsychotics have a lesser liability for excitatory postsynaptic potential and tardive dyskinesia; many do not increase prolactin. However, many of them have the risk of weight gain with its associated medical problems. Some patients, however, require maintenance treatment with antipsychotic medication.

Acute Bipolar Depression

Lithium. There is limited evidence for lithium in bipolar depression. Early studies were promising, but later placebo-controlled studies did not confirm lithium's efficacy. More extensive studies that included lithium did suggest that lithium was at least as useful as other mood stabilizers for bipolar depression.

Anticonvulsants. The most promising anticonvulsant has been lamotrigine, which has several reasonable studies showing efficacy for bipolar depression. Its major limitation is that it must be titrated gradually to prevent a severe

skin rash. Evidence for valproate and other anticonvulsants is limited. Gabapentin and levetiracetam appear to be ineffective.

Antipsychotics. Several of the atypical antipsychotics have shown efficacy for bipolar depression. Quetiapine has the best evidence. It appears that quetiapine, in a modest dose (300 mg/day), is sufficient to improve symptoms. Olanzapine, lurasidone, and cariprazine also have positive studies, and the FDA approved lurasidone for this indication. Ziprasidone and aripiprazole do not appear to be effective.

Antidepressants. It remains controversial whether antidepressants are useful for the depressive phase of bipolar disorder. This is particularly true in patients with rapid cycling and mixed states. They seem to be less effective than for major depressive disorder and may induce cycling, mania, or hypomania. The risk of inducing mania seems highest for tricyclic antidepressants, monoamine oxidase inhibitors, and perhaps the serotonin norepinephrine reuptake inhibitors such as venlafaxine. Most experts agree that antidepressants are not appropriate as monotherapy for patients with bipolar disorder.

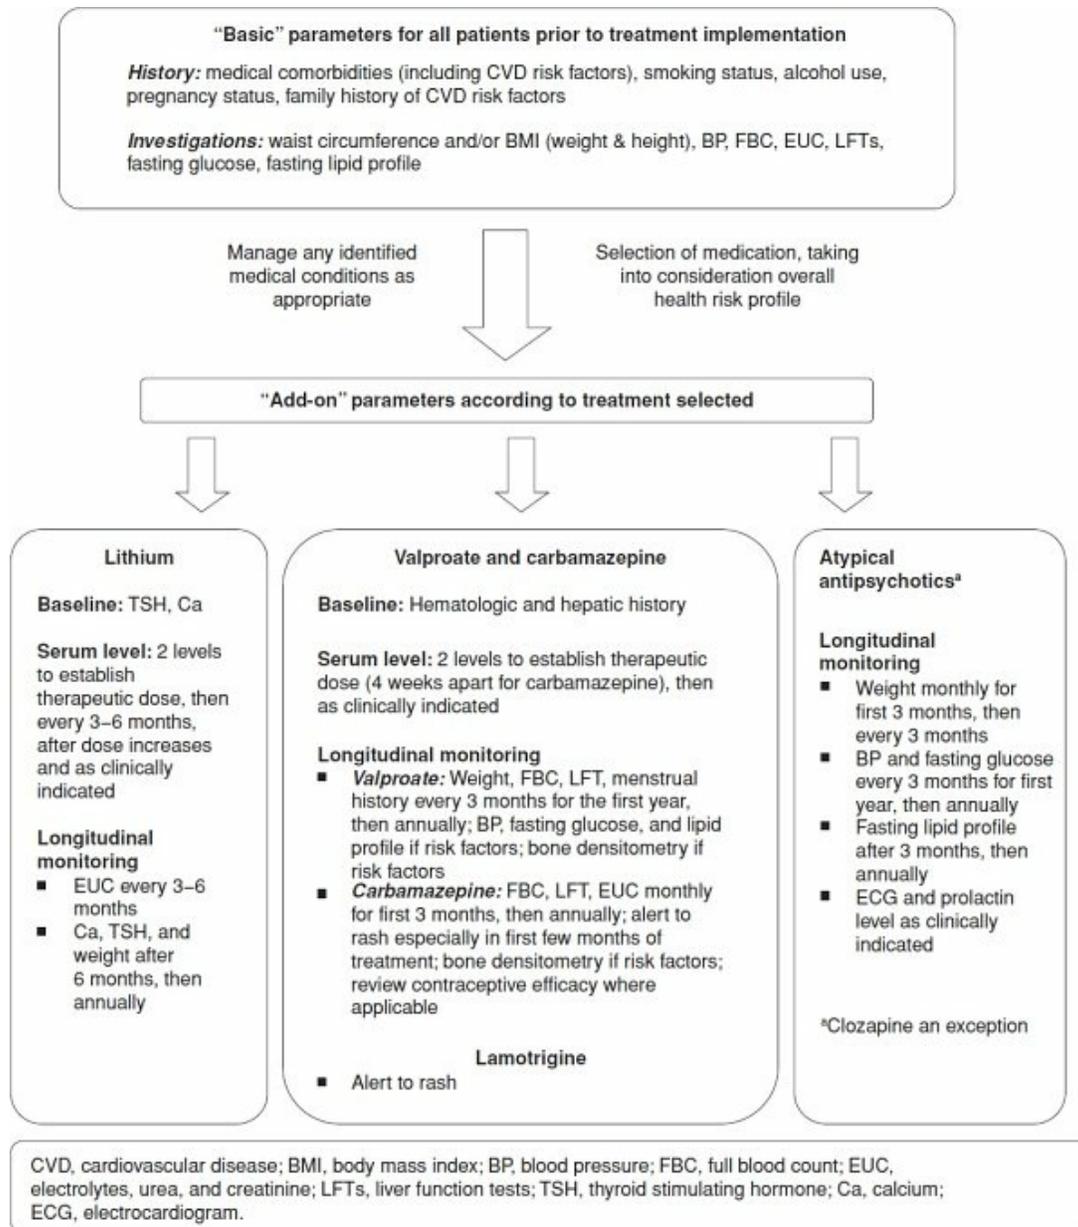
Whether we can use them as adjuncts is also controversial. Some antidepressants have some evidence of efficacy for adjunctive therapy, such as fluoxetine. On the whole, the available evidence suggests they may have some usefulness when combined with a mood stabilizer.


FIGURE 6-2
Recommendations for treatment monitoring in bipolar disorder. (Used with permission from ISBD safety monitoring guidelines.)

Electroconvulsive Therapy. Electroconvulsive therapy may also be useful for patients with bipolar depression who do not respond to lithium or other mood stabilizers and their adjuncts, particularly in cases in which strong suicidal tendency presents as a medical emergency.

Other Agents. Various clinicians and researchers have tried many other agents in an attempt to find more options for treatment. Most studies have not

been promising. Dopamine agonists, including modafinil and armodafinil, have some preliminary evidence. Omega-3-fatty acid adjunctive therapy has conflicting evidence. N-acetylcysteine (a glutathione precursor) has some preliminary evidence. Ketamine and other glutamatergic modulators may have a role in treatment-resistant patients.

Table 6-7
Atypical Antipsychotics for Bipolar Disorder: Efficacy Summary and Dose Ranges

Drug	Dose Range (mg)	Efficacy					Comments
		Acute Mania	Acute Bipolar Depression	Prophylaxis			
				Mood Episodes	Mania	Depression	
Olanzapine	5–20	Yes	Yes (see comments)	Yes	Yes	Yes	Improvement was seen mostly in sleep, appetite, and inner tension but not in core depressive symptoms Magnitude of benefit for depression less than for mania
Risperidone	1–6	Yes	No data	Yes	Yes	No	Prophylactic efficacy was demonstrated with Risperdal Consta but no studies with oral risperidone
Quetiapine	300–800	Yes	Yes	Yes	Yes	Yes	For bipolar depression, 300 mg/day is as effective as 600 mg/day (see text for guidance) Appears to have equal efficacy in preventing both mania and depression
Ziprasidone	80–160	Yes	No	Yes	Yes	No	Prophylaxis demonstrated for adjunctive therapy but no data for monotherapy
Aripiprazole	15–30	Yes	No	Yes	Yes	No	
Paliperidone	6–12	Yes	No data	Yes	Yes	No	Less effective than olanzapine in preventing mood episodes
Asenapine	10–20	Yes	No data	Yes	Yes	Yes	Numerically fewer patients in the asenapine group had relapse of manic and depressive episodes but the differences were not significant
Lurasidone	40–120	No data	Yes	Studies underway	Studies underway	Studies underway	Effective in depressed patients with mixed features
Cariprazine	3–12	Yes	Yes	No data	No data	No data	For bipolar depression, 1.5–3 mg/day is recommended, while for mania, up to 12 mg/day is appropriate

DURATION AND PROPHYLAXIS

Maintenance Treatment. Preventing recurrences of mood episodes is the greatest challenge facing clinicians. Not only must the chosen regimen achieve its primary goal—sustained euthymia—but the medications should not produce unwanted side effects that affect functioning. Sedation, cognitive impairment, tremor, weight gain, and rash are some side effects that lead to

treatment discontinuation.

Lithium, carbamazepine, and valproic acid, alone or in combination, are the most widely used agents for the long-term treatment of patients with bipolar disorder. For patients treated with long-term lithium, thyroid supplementation is often necessary to treat lithium-induced hypothyroidism.

Lamotrigine has prophylactic antidepressant and, potentially, mood-stabilizing properties. Lamotrigine appears to be superior at the acute and prophylactic treatment of the depressive phase of illness compared to the manic.

ACUTE TREATMENT FAILURES. Most patients will respond to treatment within 2 weeks. When they do not respond, we should consider using a different approach. When patients do not respond to initial treatment, it makes sense to try another first-line treatment as there are several from which to choose. Most patients will respond to one of these treatments, at least during their manic phase; depression may be more difficult.

SELECTING SECOND TREATMENT OPTIONS. In the rare case that first-line treatment fails, other options include haloperidol, carbamazepine, and combination treatment with lithium and valproate. If those fail, other antipsychotics could be considered.

Other Somatic Treatments. In addition to ECT (discussed above), transcranial magnetic stimulation and magnetic seizure therapy have limited, although promising, data.

Psychosocial Therapy

Psychotherapy can be a crucial adjunct for patients. The goals of this therapy include helping treatment adherence, promoting stability, and avoiding risk factors for the disorder. Cognitive-behavioral therapy, interpersonal and social rhythm therapy, and family focused therapy are all reasonable therapies to use. Table 6-8 summarizes psychotherapeutic treatments for bipolar disorder, including the presumed underlying mechanism and sample interventions.

Table 6-8

Efficacious Psychotherapeutic Treatments for Bipolar Disorder

Treatment	Conceptualization of Disorder Etiology	Sample Interventions
Cognitive-behavioral therapy	Biologic vulnerability interacting with stress Skills deficits limit ability to manage symptoms	Identify and challenge automatic thoughts that interfere with treatment adherence Engage in rewarding activities that provide increased routine and stability Practice communication skills with providers
Interpersonal and social rhythm therapy	Interpersonal vulnerabilities arising from early attachment and learned relationship patterns, plus disruption of social rhythms	Develop awareness of patterns in primary relationships and the therapeutic relationship Track and stabilize social rhythms Interpersonal skills training Communication analysis

| Family-focused therapy | Biologic vulnerability exacerbated by negative expressed emotion in family environment | Education regarding the disorder, including precipitants, risk factors, and effective treatment
Establish relapse prevention plan, agreed upon by all involved family members
Communication skills training
Problem-solving skills training |

THE EPIDEMIOLOGY OF THE DISORDER(S)

Incidence and Prevalence

We show the US prevalence rates of different clinical forms of bipolar disorder in Figure 6-3. The annual incidence of bipolar illness is usually estimated to be less than 1 percent. Worldwide it is estimated to vary from 0.3 to 1.2 percent by country. However, it is difficult to estimate because it is easy to miss milder forms of bipolar disorder.

Sex

In contrast to major depressive disorder, bipolar I disorder has a roughly equal prevalence among men and women. Manic episodes are more common in men, and depressive episodes are more common in women. When manic episodes occur in women, they are more likely than men to present a mixed picture (e.g., mania and depression). Women also have a higher rate of having the rapid cycling subtype of bipolar I disorder.

Age

The onset of bipolar I disorder is earlier than that of major depressive disorder. The age of onset for bipolar I disorder ranges from childhood (as early as age 5 or 6 years) to 50 years or even older in rare cases, with a mean age of 30 years. The overall prevalence of bipolar disorder in adolescents is similar to adults. However, it increases with age; that is, the prevalence is about 2 percent in 13- and 14-year-olds, but it doubles by age 18.

Other Factors

Bipolar I disorder is more common in divorced and single persons than among married persons, but this difference may reflect the early onset and the resulting marital discord characteristic of the disorder.

There is a higher than average incidence of bipolar I disorder in upper socioeconomic groups. Bipolar I disorder is more common in persons who did not graduate from college than in college graduates. This may also reflect the relatively early age of onset for the disorder.

THE NEUROBIOLOGY OF THE DISORDER

Similar to the depressive disorders, the most consistent abnormality observed in bipolar disorders is an increased frequency of abnormal hyperintensities in subcortical regions, such as periventricular regions, the basal ganglia, and the thalamus. We find this more commonly in bipolar I disorder than in depressed adults. These hyperintensities likely reflect the deleterious neurodegenerative effects of recurrent episodes.

Our Understanding of the Genetics of Bipolar Disorder

Studies of Inheritance Patterns. A family history of bipolar disorder conveys a higher risk for mood disorders in general and, specifically, a much greater risk for bipolar disorder. Unipolar depression is typically the most common form of mood disorder in families of bipolar probands. One large study found a threefold increase in the rate of bipolar disorder and a twofold increase in unipolar disorder in the biologic relatives of bipolar probands. First-degree relatives have an approximately 10-fold risk of developing the disorder. Twin studies suggest that the heritability is between 0.7 and 0.8.

Genetic Studies. Linkage studies have historically implicated several regions, most notably chromosomes 18q and 22q. Several linkage studies have found evidence for the involvement of specific genes in clinical subtypes. For example, the linkage evidence on 18q mainly derived from bipolar II–bipolar II sibling pairs and families that had panic symptoms.

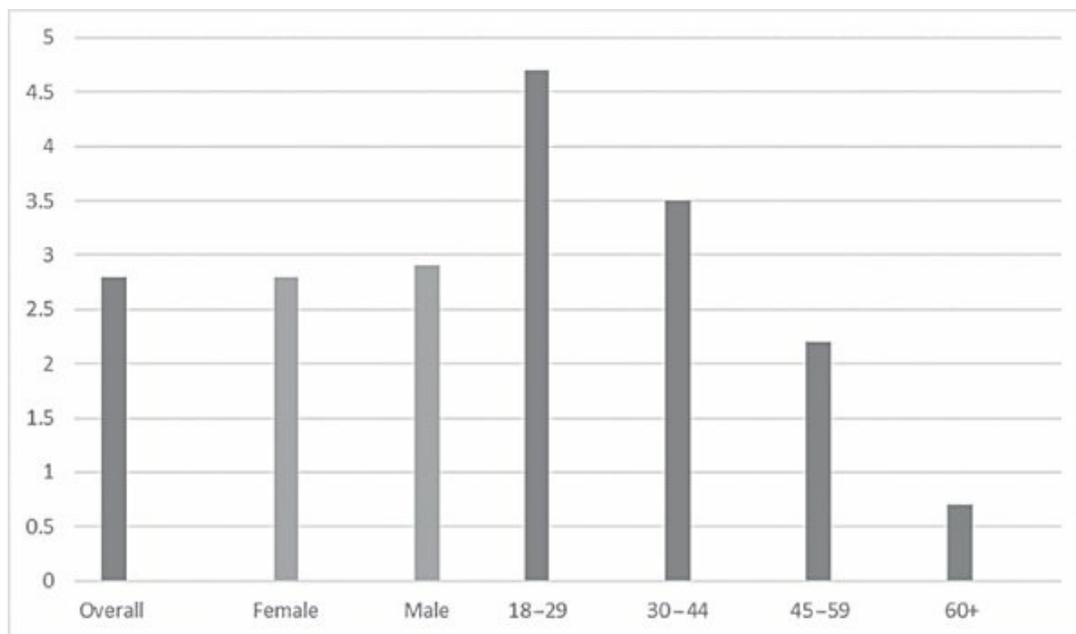
GWAS studies report an ever-growing list of associated loci. Current evidence suggests a pattern of polygenic risk—many susceptible loci, each with a small effect that contributes to the disorder. These genes do not appear to be specific to bipolar disorder but rather overlap with other severe psychiatric disorders, particularly schizophrenia. Studies have tended to focus on genes that could give clues to etiology, such as genes involved in neurodevelopment, or genes encoding for voltage-dependent calcium channels.


FIGURE 6-3
Past year prevalence of bipolar disorder in US Adults. (Data from the National Comorbidity Survey Replication [2001–2003].)

Perhaps the most important finding from genetic studies is that of the many genes found to be associated with bipolar disorder, most of them are also associated with schizophrenia.

Pathologic Imaging Findings

Structural Imaging. Individual studies have reported various areas of the brain with variations in gray matter volume, including the striatum, thalamus, amygdala, hippocampus, and pituitary—potentially meaningful findings as these are traditionally regions of interest in this disorder given their presumed functions. However, many of these are small studies with findings with conflicting results. At least one meta-analysis concluded that the evidence taken as a whole did not support morphologic differences in these areas.

There have been some consistent structural findings in other brain regions, including the inferior frontal gyrus, left insula, cerebellum, and left orbitofrontal gyrus, which are seen both in affected individuals and first-degree relatives. Although the significance of these findings is not well understood, many of these areas seem involved in emotional regulation, and the inferior frontal gyrus may have a particular role in executive function, particularly response inhibition. In several cases, the differences are of increased thickness in bipolar patients, suggesting that these brain changes may represent compensatory reactions to the disorder rather than etiologic risk factors.

Functional Imaging. There are fewer fMRI or PET studies than there are MRI studies; the majority examine the brain during the performance of various cognitive or emotional tasks and suggest either increased or decreased activations along various circuits. Consistent findings include abnormalities along a network that includes the superior and medial frontal cortex and insula, which showed increased activation compared with controls. As many of the areas are involved in executive functioning and working memory, this appears to be consistent with neuropsychological studies of the disorder. Other areas may show decreased activation, including the amygdala, basal ganglion, and limbic system. These findings may be evidence for downregulation of specific circuits, perhaps in response to the abnormal activity in the other circuits.

Inflammatory Markers

Some inflammatory markers, most notably interleukin-6, are elevated in bipolar patients. Markers of inflammation may be particularly evident during adolescence and become less evident in adulthood.

Other Neurochemical Findings. Some studies have found alterations in brain-derived neurotrophic factor, and in at least one study, this alteration may predict lithium responsiveness. Similarly, some studies of measures of oxidative stress in bipolar patients showed abnormalities that related to lithium response, however these findings are preliminary.

Assessment of the hypothalamic–pituitary–adrenal (HPA) axis suggests a dysregulated system, as evidenced by increased ACTH and cortisol levels in bipolar patients. However, these findings appear only to occur after individuals become symptomatic, suggesting that this is a result of the disorder.

THE PSYCHOLOGY OF THE DISORDER

Psychological studies have focused on neuropsychological findings, particularly of cognitive deficits associated with the disorder. Most commonly reported are deficits of executive functioning and verbal memory and learning. A variety of other related deficits, including deficits of cognitive flexibility, psychomotor speed, and attention, are also reported, although not consistently. Response inhibition is the executive function focused on the ability to prevent one's impulsive response to a situation when such a response would be inappropriate in the environmental context. This inhibition is often deficient in bipolar patients, as well as in first-degree relatives without bipolar disorder. It is particularly deficient in individuals who have bipolar disorder with psychotic features. Other executive function deficits include general impulsivity and risk-taking behavior. We see some of these same deficits with schizophrenia. However, they are less severe in schizophrenia and less likely to be recognized before the disorder appears. It may be that the cognitive deficits are indicative of a broader disorder that crosses traditional diagnostic lines and represents a spectrum of disorders defined by psychotic symptoms.

ETIOLOGY

Biologic Theories

As noted, several pathologic findings point at specific disrupted systems in the brain, particularly areas involved in the regulation of emotions and

executive functioning. What remains unclear are which findings are the results of the disorder and which are causative. For example, the significant disruptions seen in the HPA axis in patients with bipolar disorder seem to represent a neurobiologic scar that is seen only after symptoms occur.

As discussed above, converging evidence suggests that calcium signaling may be, at least in part, implicated in the disorder. The genetic abnormalities found in genes associated with voltage-gated calcium channels noted above, as well as the clinical observation that certain drugs have mechanisms of action involving calcium channels (e.g., antiepileptic drugs) lend support for such a theory. Furthermore, preclinical cellular studies show some evidence for increased intracellular calcium signaling in the neurons of bipolar patients. The evidence for calcium channel abnormalities in high risk but asymptomatic individuals, as well as first-degree relatives of patients with the disorder, suggests that this may be involved in the etiology of the disorder.

Neurodevelopment likely plays a role as well, like schizophrenia, and the fact that immunologic markers are more prevalent in bipolar individuals during adolescence than adulthood appears to support a developmental etiology for the disorder.

Psychosocial Theories

Most psychodynamic theories of mania view manic episodes as a defense against underlying depression.

Ms. G, a 42-year-old housewife and mother of a 4-year-old boy, developed symptoms of hypomania and later of frank mania without psychosis, when her only son was diagnosed with acute lymphocytic leukemia. A profoundly religious woman who had experienced 10 years of difficulty with conception, Ms. G was a devoted mother. She reported that she was usually rather down. Before her son's illness, she used to joke that she had become pregnant with him by divine intervention. When her son was diagnosed and subsequently hospitalized, he required painful medical tests and emergency chemotherapy, which made him very ill. The doctors regularly barraged Ms. G with bad news about his prognosis during the first few weeks of his illness.

Ms. G was ever present with her son at the hospital, never sleeping,

always caring for him, yet the pediatricians noted that as the child became more debilitated and the prognosis more grim, she seemed to bubble over with renewed cheerfulness, good humor, and high spirits. She could not seem to stop herself from cracking jokes to the hospital staff during her son's painful procedures, and as the jokes became louder and more inappropriate, the staff grew more concerned. During her subsequent psychiatric consultation (requested by the pediatric staff), Ms. G reported that her current "happiness and optimism" were justified by her sense of "oneness" with Mary, the mother of God. "We are together now, she and I, and she has become a part of me. We have a special relationship," she winked. Despite these statements, Ms. G was not psychotic and said that she was "speaking metaphorically, of course, only as a good Catholic would." Her mania resolved when her son achieved remission and was discharged from the hospital. (Courtesy of JC Markowitz, M.D. and BL Milrod, M.D.)

However, such approaches to understanding bipolar disorder have become less accepted as the biologic evidence has mounted. The role of the environment, particularly psychosocial stress, is likely crucial in the etiology. Karl Abraham, for example, believed that the manic episodes might reflect an inability to tolerate a developmental tragedy, such as the loss of a parent. The manic state may also result from a tyrannical superego, which produces excessive self-criticism that is then replaced by euphoric self-satisfaction. Bertram Lewin regarded the manic patient's ego as overwhelmed by pleasurable impulses, such as sex, or by feared impulses, such as aggression. Melanie Klein also viewed mania as a defensive reaction to depression, using manic defenses such as omnipotence, in which the person develops delusions of grandeur.

Depressive Disorders

THE CLINICAL PRESENTATION

A depressed mood and a loss of interest or pleasure are the key symptoms of depression. Patients may say that they feel blue, hopeless, in the dumps, or worthless. For a patient, the depressed mood often has a distinct quality that differentiates it from the normal emotion of sadness or grief. Patients often describe the symptom of depression as one of agonizing emotional pain. Alternately they perceive it as a physical illness in which they feel exhausted and unmotivated. Others report feeling little, being unable to cry, and finding it difficult to experience any pleasure.

The classic presentation of a depressed patient is a person with a stooped posture, decreased movement, and a downward averted gaze. In practice, there is a considerable range of behaviors ranging from persons with no observable symptoms to the catatonically depressed patient. Among observable signs of depression, generalized psychomotor retardation is the most often described, in which patients show little spontaneous movement. At times it may be so severe as to be challenging to differentiate from catatonia.

Ms. A, a 34-year-old literature professor, presented to a mood clinic with the following complaint: "I am in a daze, confused, disoriented, staring. My thoughts do not flow, my mind is arrested.… I seem to lack any sense of direction, purpose.… I have such an inertia, I cannot assert myself. I cannot fight; I have no will."

Psychomotor agitation may occur, including such behaviors as hand wringing and hair pulling. Many depressed patients have a decreased rate and volume of speech; they respond to questions with single words and exhibit delayed responses to questions.

When present, observable symptoms are helpful in the diagnosis; however, the lack of such symptoms does not imply that a patient has no disorder. It is not abnormal, for example, to encounter patients who can maintain a measure of social appropriateness, even smiling and laughing when with others, despite feeling internally miserable.

The most typical somatic symptoms of depression are called the *neurovegetative symptoms of depression* and typically include a variety of physical symptoms. Table 7-1 lists typical neurovegetative symptoms.

Almost all depressed patients (97 percent) complain about reduced energy; they have difficulty finishing tasks, are impaired at school and work, and have less motivation to undertake new projects. About 80 percent of patients complain of trouble sleeping, especially early morning awakening (i.e., terminal insomnia) and multiple awakenings at night, during which they ruminate about their problems. Many patients have decreased appetite and weight loss, but others experience increased appetite and weight gain and sleep longer than usual. These are sometimes called *reversed neurovegetative symptoms* or *atypical features*.

Depression is, by definition, a mood disorder, and disturbances of mood are at the core. Patients feel "bad" and may use words such as "sad," "depressed," "blue," "down," or similar words to describe this feeling. Here we use the term *dysphoria* to encompass these various depressive feelings as a way to avoid the confusion inherent in using the word "depressed" to mean both the diagnosis and the core symptom. Also, many patients are reluctant to use the word "depressed" as they may have difficulty coming to terms with their diagnosis. In such cases, other synonyms, including those above, may seem less threatening to the patient.

Some patients deny dysphoria altogether, but instead, describe feeling unable to enjoy things that are usually enjoyable to them. We call this *anhedonia* or a lack of pleasure. In addition to dysphoria and anhedonia, many depressed patients also report feeling anxious.

The critical point is that although sadness and even depression may be, in themselves, normal reactions, when encountered in the context of a

depressive disorder, patients do not experience them as normal. Patients will often feel genuinely ill and be able to distinguish their emotional state from "normal" feelings of sadness. Many will first interpret this as indicative of medical illness and present to their primary care doctor complaining of feeling "sick" rather than depressed.

Depressed patients customarily have negative views of the world and themselves. Their thought content often includes nondelusional ruminations about loss, guilt, suicide, and death. About 10 percent of all depressed patients have marked symptoms of a thought disorder, usually thought blocking and profound poverty of content.

> A 42-year-old civil servant said that she was so paralyzed by depression that she felt that she had no personal initiative and volition left; she believed that some malignant force had taken over her actions and that it was commenting on every action that she was undertaking. The patient recovered fully with thymoleptic medication. There is no reason to believe that, in this patient, the feelings of somatic passability and running commentary indicated a schizophrenic process.

Depressed patients may complain of either delusions or hallucinations associated with their depressive episode: such patients may have a major depressive episode with psychotic features, often called psychotic depression. Delusions and hallucinations that are consistent with a depressed mood are said to be mood-congruent. Mood-congruent delusions in a depressed person include those of guilt, sinfulness, worthlessness, poverty, failure, persecution, and terminal somatic illnesses (such as cancer and a "rotting" brain). The content of mood-incongruent delusions or hallucinations is not consistent with a depressed mood. For example, a mood-incongruent delusion in a depressed person might involve grandiose themes of exaggerated power, knowledge, and worth.

Table 7-1
Neurovegetative Symptoms of Depression

Common:

Fatigue, low energy
Inattention
Insomnia, early morning awakening
Poor appetite, associated weight loss

Sometimes included:
Decreased libido and sexual performance
Menstrual irregularities
Worse depression in the AM

About two-thirds of all depressed patients contemplate suicide, and 10 to 15 percent commit suicide. Those recently hospitalized with a suicide attempt or suicidal ideation have a higher lifetime risk of successful suicide than those never hospitalized for suicidal ideation.

Depressed patients with psychotic features occasionally consider killing a person as a result of their delusional systems, but the most severely depressed patients often lack the motivation or the energy to act impulsively or violently. Patients with depressive disorders are at increased risk of suicide as they begin to improve and regain the energy needed to plan and carry out suicide (paradoxical suicide).

About 50 to 75 percent of all depressed patients have some measure of cognitive impairment. Cognitive symptoms include subjective reports of an inability to concentrate (84 percent of patients in one study) and impairments in thinking (67 percent of patients in another study).

Most depressed patients are oriented, although some may not have sufficient energy or interest to answer questions about these subjects during an interview. Memory can be challenging to disentangle from concentration difficulties. However, some patients appear to have genuine memory difficulties in addition to other cognitive deficits.

Some depressed patients sometimes seem unaware of their depression and do not complain of a mood disturbance even though they exhibit withdrawal from family, friends, and activities that previously interested them. Other depressed patients, particularly those with disordered thoughts, may be overly negative, hyperbolic in their symptomatic description, and hopeless about their future. It may be difficult to convince such patients that improvement is

possible.

We can assess judgment by reviewing patients' actions in the recent past and their behavior during the interview. Patients with particularly negative outlooks should be cautioned not to make important life decisions (e.g., around a relationship or job) until they are "thinking normally" again.

In interviews and conversations, depressed patients may emphasize the bad and minimize the good. They may be pessimistic about past treatment trials. A common clinical mistake is to unquestioningly believe a depressed patient who states that a previous trial of antidepressant medications did not work. Such statements may be false, and they require a confirmation from another source. Psychiatrists should not view patients' misinformation as an intentional fabrication; the admission of any hopeful information may be impossible for a person in a depressed state of mind.

Other patients, particularly those with poor insight, may have difficulty reporting symptoms or past episodes. Asking about changes in functioning rather than emotional states may be helpful ("have there been times that you felt unable to work, or care for your children?").

Presentation in Special Populations

Depression in Children and Adolescents. School phobia and excessive clinging to parents may be symptoms of depression in children. Poor academic performance, substance abuse, antisocial behavior, sexual promiscuity, truancy, and running away may be symptoms of depression in adolescents.

Depression in Older People. Depression is more common in older persons than it is in the general population. Various studies have reported prevalence rates ranging from 25 to almost 50 percent, although the percentage of these cases that are caused by major depressive disorder is uncertain. Several studies indicate that depression in older persons correlates with low socioeconomic status, the loss of a spouse, a concurrent physical illness, and social isolation. Other studies have indicated that depression in older persons is underdiagnosed and undertreated, perhaps particularly by general practitioners. The underrecognition of depression in older persons may occur because the disorder appears more often with somatic complaints

in older than in younger, age groups. Further, ageism may influence and cause clinicians to accept depressive symptoms as usual in older patients.

DIAGNOSIS

Depressive disorders can take many forms, depending on their severity and chronicity. The disorder that we most associate with "classic" depression is major depressive disorder, and this is the disorder most often referred to when someone reports that they suffer from depression. However, it is essential to understand the different varieties of depressive disorders, including those not included in some formal classifications, as all are significant sources of morbidity.

Major Depressive Disorder

The primary feature of major depressive disorder is the occurrence of at least one episode of major depression, which is significant depressive symptoms that last for a significant time. Table 7-2 compares the different approaches to diagnosing major depressive disorder.

With Psychotic Features. The presence of psychotic features in major depressive disorder reflects severe disease and is a poor prognostic indicator. We often categorize psychotic symptoms as either mood-congruent, that is, in harmony with the mood disorder ("I deserve punishment because I am so bad"), or mood-incongruent, not in harmony with the mood disorder. Patients with mood-incongruent psychotic symptoms may be more likely to have a comorbid primary psychotic disorder, such as schizoaffective disorder or schizophrenia.

With Melancholic Features. Melancholia is one of the oldest terms used in psychiatry, dating back to Hippocrates in the 4th century to describe the dark mood of depression. We still use it to refer to a depression characterized by severe anhedonia, early morning awakening, weight loss, and profound feelings of guilt (often over trivial events). It is not uncommon for patients who are melancholic to have suicidal ideation. Melancholia is associated with changes in the autonomic nervous system and endocrine functions. For that reason, we sometimes refer to melancholia as "endogenous depression" or

depression that arises in the absence of external life stressors or precipitants.

Table 7-2
Major Depressive Disorder

	DSM-5	ICD-10
Diagnostic name	Major Depressive Disorder	Major Depressive Episode
Duration	2 wk	
Symptoms	• Dysphoria or feeling depressed • Anhedonia • ↑ or ↓ weight or appetite • ↑ or ↓ sleep • ↑ or ↓ activity • ↓ energy • Depressing thoughts: worthlessness, guilt • ↓ concentration • Suicidal ideation/plan	• ↓ mood • ↓ energy • ↓ activity • ↓ capacity for enjoyment • ↓ interest • ↓ concentration • Fatigue after even minimal effort • Disturbed sleep/early morning awakening • Disturbed appetite/ ↓ weight • ↓ self esteem • ↓ self-confidence • Guilt or worthlessness • Mood unreactive to circumstances • Anhedonia • Worse symptoms in the AM • Psychomotor disturbance: agitation or retardation

		• ↓ libido
Required number of symptoms	5 (1 has to be one of the first two listed)	
Psychosocial consequences of symptoms	Distress or impaired functioning (social, occupational, or other significant areas)	Depends on severity
Exclusions (Not better explained by):	Medical illness Substance Other psychiatric disorder History of mania or hypomania	Adjustment disorder Conduct disorder Recurrent depressive disorder (which is considered a separate diagnosis)

Symptom specifiers	**With anxious distress**
	• 2+ symptoms of anxiety
	With mixed features
	• 3+ manic/hypomanic symptoms *during* the depressive episode (if occur independently, diagnose bipolar disorder)
	With melancholic features
	• Loss of pleasure or reactivity to pleasure
	• 3+ of the following
	  • Severe depression/despair
	  • Mood worse in AM
		Depressive reaction
		Psychogenic depression
		Reactive depression

- Early morning awakening
- Psychomotor disturbance
- Anorexia/weight loss
- Guilt

With atypical features
- Mood reactivity
- 2+ of following
  - Increased appetite/weight
  - Hyposomnia
  - Leaden paralysis
  - Rejection sensitivity

With mood-congruent psychotic features

With mood-incongruent psychotic features

With catatonia
- Must be present during most of depressive episode

With peripartum onset

With seasonal pattern
- Usually occurs during a specific season

Course specifiers	**With psychotic features** - Psychotic symptoms occurring only during the depressive	**Recurrent Depressive Disorder** (Coded as separate disorder): Repeated episodes of the above symptoms.

	episode • Mood-congruent • Mood-incongruent **In partial remission** • Full criteria no longer met **In full remission** • 0 symptoms for 2 mo	No mania.
Severity specifiers	**Mild:** minimal symptoms **Moderate:** between mild and severe **Severe:** # of symptoms and severity/dysfunction well beyond that required for diagnosis	**Mild** • 2–3 symptoms • Functions normal despite distress **Moderate** • 4+ symptoms • Difficulty with functioning **Severe** • Several symptoms marked and distressing • Loss of self-esteem/feels worthless and guilty • Suicidal ideation/acts • Somatic symptoms of depression **Severe with psychotic symptoms** • As above but with psychosis **Other** • Atypical depression

- Single episodes of "masked depression"

Unspecified

With Atypical Features. Patients with major depressive disorder with atypical features have specific, predictable characteristics. As described above, these tend to be the reverse of the neurovegetative symptoms. They may, for example, overeat or oversleep. Patients with atypical features have a younger age of onset and more severe psychomotor slowing. They also are more likely to have comorbid disorders, including anxiety disorders, substance use disorder, or somatic symptom disorder. They are easy to misdiagnose as having an anxiety disorder rather than a mood disorder. Patients with atypical features may also have a long-term course, a diagnosis of bipolar I disorder, or a seasonal pattern to their disorder.

Kevin, a 15-year-old adolescent, was referred to a sleep center to rule out narcolepsy. His main complaints were fatigue, boredom, and a need to sleep all the time. Although he had always started the day somewhat slowly, he now could not get out of bed to go to school. That alarmed his mother, prompting sleep consultation. Formerly a B student, he had been failing most of his courses in the 6 months before referral. Psychological counseling, predicated on the premise that his family's recent move from another city had led to Kevin's isolation, had not been beneficial. Extensive neurologic and general medical workup findings had also proven negative. He slept 12 to 15 hours per day but denied cataplexy, sleep paralysis, and hypnagogic hallucinations. During psychiatric interview, he denied being depressed but admitted that he had lost interest in everything except his dog. He had no drive, participated in no activities, and had gained 30 lb in 6 months. He believed that he was "brain damaged" and wondered whether it was worth living like that. The question of suicide disturbed him because it was contrary to his religious beliefs. These findings led to the prescription of an antidepressant. Not only did the antidepressant reverse the presenting complaints, but it also pushed him to the brink of a manic episode. (Courtesy of HS Akiskal, M.D.)

With Catatonic Features. As a symptom, catatonia can be present in several mental disorders, most commonly, schizophrenia and mood disorders. The hallmark symptoms of catatonia are stupor, blunted affect, extreme withdrawal, negativism, and marked psychomotor retardation. The presence of catatonic features in patients with mood disorders may have prognostic and treatment significance.

Postpartum Onset. We diagnose the postpartum subtype if the onset of symptoms is within 4 weeks postpartum. Postpartum mental disorders commonly include psychotic symptoms.

Seasonal Pattern. Patients with a seasonal pattern to their mood disorders tend to experience depressive episodes during a particular season, most commonly winter. The pattern has become known as seasonal affective disorder (SAD), although DSM-5 does not use this term. There is some controversy regarding whether this represents a subtype of major depressive disorder or a distinct entity. Either way, the presence of the disorder has implications for treatment, as patients with a seasonal pattern to their depression may preferentially respond to light therapy.

Dysthymic Disorder

Dysthymic disorder (also called dysthymia) is the presence of depressive symptoms that are less severe than those of major depressive disorder. Although less severe than a major depressive disorder, it is often more chronic. Table 7-3 compares the different approaches to diagnosing.

The most typical feature of dysthymia, also known as persistent depressive disorder, is the presence of a depressed mood that lasts most of the day and is present almost continuously. There are associated feelings of inadequacy, guilt, irritability, and anger; withdrawal from society; loss of interest; and inactivity and lack of productivity. The term dysthymia, which means "ill-humored," was introduced in 1980. Before that time, we tended to classify patients having dysthymia as having "neurotic depression."

Dysthymia is distinguished from major depressive disorder by the fact that patients complain that they have always been depressed. Thus, most cases are

of early-onset, beginning in childhood or adolescence, and, almost always, by a patient's 20s.

Table 7-3
Dysthymic Disorder

	DSM-5	ICD-10
Diagnostic name	Persistent Depressive Disorder	Dysthymia [F43.1]
Duration	2+ yr (1+ yr for children) ≤2-mo symptom free during illness	
Symptoms	Depressed mood most of the time ↓ appetite ↓ or ↑ sleep ↓ energy ↓ self-esteem ↓ concentration/decision-making ability Hopelessness	Chronically depressed mood that does not meet criteria for a depressive episode, though criteria may have been met in the past
Required number of symptoms	First symptom and 2+ of rest	
Psychosocial consequences of symptoms	Distress and functional impairment	
Exclusions	History of bipolar disorder Another mental illness Substance Another medical illness	Anxiety Depression Bereavement Schizophrenia
Symptom	**With pure dysthymic**	

specifiers	**syndrome:** criteria for depressive episode not met in the last 2 yr
	With persistent major depressive episode: has met diagnostic criteria for a depressive episode for entire 2-yr period
	With intermittent major depressive episode, with current episode: in current episode, 8 wk+ in last 2 yr with subdiagnostic symptoms episode
	With intermittent major depressive episode, without current episode: Not currently in episode, 1+ depressive episode in past 2 yr
	With anxious distress *≥2 of following:* • Feeling tense • Restlessness • ↓ concentration due to worrying • ↑ fear without apparent cause • Fear of loss of control
	With mixed features —depressive or manic/hypomanic

	episode, + with additional symptoms of other episode but subdiagnostic **With melancholic features:** see Table 7-2 **With atypical features:** see Table 7-2 **With psychotic features** • Mood-congruent • Mood-incongruent
Course specifiers	**With peripartum onset—** episode is during pregnancy or ≤4 wk after delivery
Severity specifiers	**Mild:** minimal symptoms **Moderate:** between mild and severe **Severe:** # of symptoms and severity/dysfunction well beyond that required for diagnosis

A 27-year-old male grade-school teacher presented with the chief complaint that life was a painful duty that had always lacked luster for him. He said that he felt "enveloped by a sense of gloom" that was nearly always with him. Although he was respected by his peers, he felt "like a grotesque failure, a self-concept I have had since childhood." He stated that he merely performed his responsibilities as a teacher and that he had never derived any pleasure from anything he had done in life. He said that he had never had any romantic feelings; sexual activity, in which he

had engaged with two different women, had involved pleasureless orgasm. He said that he felt empty, going through life without any sense of direction, ambition, or passion, a realization that itself was tormenting. He had bought a pistol to put an end to what he called his "useless existence" but did not carry out suicide, believing that it would hurt his students and the small community in which he lived. (Courtesy of HS Akiskal, M.D.)

A late-onset subtype, much less prevalent and not well characterized clinically, has been identified among middle-aged and geriatric populations, mainly through epidemiologic studies in the community.

The family history of patients with dysthymia is typically replete with both depressive and bipolar disorders, which is one of the more robust findings supporting its link to primary mood disorder.

Other Diagnoses

Minor Depressive Disorder. Minor depressive disorder consists of episodes of depressive symptoms that are less severe than those seen in major depressive disorder. The difference between dysthymia and minor depressive disorder is primarily the episodic nature of the symptoms in the latter. Between episodes, patients with minor depressive disorder have a euthymic mood, but patients with dysthymia have virtually no euthymic periods. DSM-5 does not include this diagnosis. However, ICD-10 includes it as a mild type of depressive episode. DSM-5 would diagnose it as an "Other Specified Depressive Disorder."

Recurrent Brief Depressive Disorder. Recurrent brief depressive disorder consists of brief periods (less than 2 weeks) during which depressive episodes are present. Patients with the disorder would meet the diagnostic criteria for a major depressive disorder if their episodes lasted longer. Patients with recurrent brief depressive disorder differ from patients with dysthymia on two counts: they have an episodic disorder, and their symptoms are more severe. ICD-10 lists this as an "Other Recurrent Mood Disorder," whereas DSM-5 would diagnose it as an "Other Specified Depressive Disorder."

Double Depression. An estimated 40 percent of patients with major depressive disorder also meet the criteria for dysthymia, a combination often referred to as a double depression. Available data support the conclusion that patients with double depression have poorer prognoses than patients with major depressive disorder alone. The treatment of patients with double depression should be directed toward both disorders because the resolution of the symptoms of major depressive episode still leaves these patients with significant psychiatric impairment.

Objective Rating Scales for Depression

There is a growing literature suggesting that the use of objective scales can significantly improve the reliability of depressive diagnoses. They can also be useful for tracking the course of an episode. Several validated scales exist.

Clinician Administered Scales. The Hamilton Rating Scale for Depression (HAM-D) is a widely used depression scale. It contains up to 24 items, each rated on a 0 to 4 or 0 to 2 scale. The clinician evaluates the patient's answers to questions about feelings of guilt, thoughts of suicide, sleep habits, and other symptoms of depression, and derives the ratings from that interview. The usual scoring cutoffs are 10 to 13 for mild depression, 14 to 17 for mild-to-moderate depression, and >17 for moderate-to-severe depression.

Self-Administered Scales. The Zung Self-Rating Depression Scale is a 20-item report scale. A normal range is 34 or less; a depressed score is 50 or more. The scale provides a global index of the intensity of a patient's depressive symptoms, including the affective expression of depression.

The Raskin Depression Scale is a clinician-rated scale that measures the severity of a patient's depression, as reported by the patient and as observed by the physician, on a 5-point scale of three dimensions: verbal report, displayed behavior, and secondary symptoms. The scale has a range of 3 to 13; a normal score is 3, and a depressed score is 7 or more.

DIFFERENTIAL DIAGNOSIS

The symptoms of depressive disorders commonly overlap with other

syndromes and disorders. As a result, the differential is wide. Often a careful history and examination will make the differential clear. In other cases, one may have to observe the disorder over time before the diagnosis becomes clear.

General Medical Disorders

It is essential to consider whether a patient's depression is due to a general medical condition. Failure to obtain a good clinical history or to consider the context of a patient's current life situation can lead to diagnostic errors. Clinicians should have depressed adolescents tested for mononucleosis, and we should test patients who are markedly overweight or underweight for adrenal and thyroid dysfunctions. We should test patients with appropriate risk factors for HIV, and older patients for viral pneumonia and other medical conditions.

Table 7-4 lists some pharmacologic and medical conditions that can cause depression.

Table 7-4
Pharmacologic Factors and Physical Diseases Associated with Onset of Depression

Pharmacologic
   Steroidal contraceptives
   Reserpine, methyldopa
   Anticholinesterase insecticides
   Amphetamine or cocaine withdrawal
   Alcohol or sedative–hypnotic withdrawal
   Cimetidine, indomethacin
   Phenothiazine antipsychotic drugs
   Thallium, mercury
   Cycloserine
   Vincristine, vinblastine
   Interferon

Endocrine–metabolic[a]
  Hypothyroidism and hyperthyroidism
  Hyperparathyroidism
  Hypopituitarism
  Addison disease
  Cushing syndrome
  Diabetes mellitus

Infectious
  General paresis (tertiary syphilis)
  Toxoplasmosis
  Influenza, viral pneumonia
  Viral hepatitis
  Infectious mononucleosis
  Acquired immune deficiency syndrome

Collagen
  Rheumatoid arthritis
  Lupus erythematosus

Nutritional
  Pellagra
  Pernicious anemia

Neurologic
  Multiple sclerosis
  Parkinson disease
  Head trauma
  Complex partial seizures
  Sleep apnea
  Cerebral tumors
  Cerebrovascular infarction (and disease)

Neoplastic

Abdominal malignancies
Disseminated carcinomatosis

[a]Cholesterol is not mentioned because low levels as a factor in depression have been inconsistently reported.

Many neurologic and medical disorders and pharmacologic agents can produce symptoms of depression. Patients with depressive disorders often first visit their general practitioners with somatic complaints. We can detect most medical causes of depressive disorders with a comprehensive medical history, a complete physical and neurologic examination, and routine blood and urine tests. The workup should include tests for thyroid and adrenal functions because disorders of both of these endocrine systems can appear as depressive disorders. In substance-induced mood disorder, a reasonable rule of thumb is that any drug a depressed patient is taking should be considered a potential factor in the mood disorder. Cardiac drugs, antihypertensives, sedatives, hypnotics, antipsychotics, antiepileptics, antiparkinsonian drugs, analgesics, antibacterials, and antineoplastics are all commonly associated with depressive symptoms.

Neurologic Conditions

The most common neurologic problems that manifest depressive symptoms are Parkinson disease, dementing illnesses, epilepsy, cerebrovascular diseases, and tumors. About 50 to 75 percent of all patients with Parkinson disease have marked symptoms of depressive disorder that do not correlate with the patient's physical disability, age, or duration of illness but do correlate with the presence of abnormalities found on neuropsychological tests. The motor symptoms of Parkinson disease can mask a depressive disorder as the motor symptoms are similar. Depressive symptoms often respond to antidepressant drugs or ECT. The interictal changes associated with temporal lobe epilepsy can mimic a depressive disorder, especially if the epileptic focus is on the right side. Depression is a frequent complicating feature of cerebrovascular diseases, particularly in the 2 years after the episode. Depression is more common in anterior brain lesions than in posterior brain lesions and, in both cases, often responds to antidepressant medications. Tumors of the diencephalic and temporal regions are

particularly likely to be associated with depressive disorder symptoms.

Dementia. Major depressive disorder can have a profound effect on concentration and even memory, and can occasionally be confused with a neurodegenerative illness such as Alzheimer disorder. At times the term "pseudodementia" has been used to describe this. However, that may be ill-advised as it implies that the cognitive symptoms are not genuine, which is not the case. Clinicians can usually differentiate cognitive symptoms of a major depressive disorder from the dementia of a disease, such as dementia of the Alzheimer type, on clinical grounds. The cognitive symptoms in major depressive disorder have a sudden onset, and other symptoms of the disorder, such as self-reproach, are also present. A diurnal variation in the cognitive problems, not seen in primary dementias, may occur. Whereas depressed patients with cognitive difficulties often do not try to answer questions, patients with dementia may confabulate. During an interview, depressed patients can sometimes be coached and encouraged into remembering, an ability that demented patients lack.

Other Mental Disorders

Depression can be a feature of virtually any mental disorder.

Other Mood Disorders. Clinicians must consider a range of diagnostic categories before arriving at a final diagnosis. We should determine whether a patient has had episodes of mania-like symptoms, which might indicate any one of the bipolar disorders. The depressive episode of a bipolar disorder may be identical to that of a major depressive disorder. However, there may be certain features that are more predictive of a bipolar disorder, and we list these in Table 7-5.

Table 7-5
Features of a Depressive Episode that Are More Predictive of Bipolar Disorder

Early age at onset

Psychotic depression before 25 yr of age

Postpartum depression, especially one with psychotic features

Rapid onset and offset of depressive episodes of short duration (less than 3 mo)

Recurrent depression (more than five episodes)

Depression with marked psychomotor retardation

Atypical features (reverse vegetative signs)

Seasonality

Bipolar family history

High-density three-generation pedigrees

Trait mood lability (cyclothymia)

Hyperthymic temperament

Hypomania associated with antidepressants

Repeated (at least three times) loss of efficacy of antidepressants after initial response

Depressive mixed state (with psychomotor excitement, irritable hostility, racing thoughts, and sexual arousal *during* major depression)

From Akiskal. Mood disorders. In: Sadock BJ, Sadock VA, Ruiz P, eds. *Kaplan & Sadock's Comprehensive Textbook of Psychiatry*. 10th ed. Philadelphia, PA: Wolters Kluwer; 2017.

If a patient's symptoms are solely depressive, the patient most likely has a depressive disorder. Even then, we must differentiate between the various depressive disorders discussed in this chapter. To do this, we must understand the severity and the course of the disorder in detail.

Other Mental Disorders. Substance-related disorders, psychotic disorders (Table 7-6), eating disorders, adjustment disorders, and somatoform disorders are all commonly associated with depressive symptoms and should be considered in the differential diagnosis of a patient with depressive symptoms.

Perhaps the most challenging differential is that between anxiety disorders with depression and depressive disorders with marked anxiety. Table 7-7 compares the unique features of depression with those of anxiety.

Table 7-6
Common Causes of Misdiagnosis of Mood Disorder as Schizophrenia

Reliance on cross-sectional rather than longitudinal picture

Incomplete interepisodic recovery equated with schizophrenic defect

Equation of bizarreness with schizophrenic thought disorder

Ascribing irritable and cantankerous mood to paranoid delusions

Mistaking depressive anhedonia and depersonalization for schizophrenic emotional blunting

Flight of ideas perceived as loose associations

Lack of familiarity with the phenomenologic approach in assessing affective delusions and hallucinations

Heavy weight given to incidental Schneiderian symptoms

Adapted from Akiskal HS, Puzantian VR. Psychotic forms of depression and mania. *Psychiatr Clin North Am*. 1979;2:419.

Table 7-7
Unique Cross-Sectional Profiles of Clinical Anxiety and Depression

Anxiety	Depression
Hypervigilance	Psychomotor retardation
Severe tension and panic	Severe sadness
Perceived danger	Perceived loss
Phobic avoidance	Loss of interest—anhedonia

Doubt and uncertainty	Hopelessness—suicidal
Insecurity	Self-deprecation
Performance anxiety	Loss of libido
	Early-morning awakening
	Weight loss

Uncomplicated Bereavement. Uncomplicated bereavement is not a mental disorder even though about one-third of all bereaved spouses for a time meet the diagnostic criteria for major depressive disorder. Some patients with uncomplicated bereavement do develop a major depressive disorder, but we do not make this diagnosis unless the grief does not resolve. The severity and course of symptoms are significant differences. Table 7-8 lists features that would indicate that normal bereavement has progressed to a depressive disorder.

A 75-year-old widow was brought to treatment by her daughter because of severe insomnia and total loss of interest in daily routines after her husband's death 1 year before. She had been agitated for the first 2 to 3 months and thereafter "sank into total inactivity—not wanting to get out of bed, not wanting to do anything, not wanting to go out." According to her daughter, she was married at 21 years of age, had four children, and had been a housewife until her husband's death from a heart attack. Her past psychiatric history was negative; premorbid adjustment had been characterized by compulsive traits. During the interview, she was dressed in black; appeared moderately slowed; and sobbed intermittently, saying "I search everywhere for him …. I don't find him." When asked about life, she said, "Everything I see is black." Although she expressed no interest in food, she did not seem to have lost an appreciable amount of weight. The patient declined psychiatric care, stating that she "preferred to join her husband rather than get well." She was too religious to commit

suicide, but by refusing treatment, she felt that she would "pine away … find relief in death and reunion." (Courtesy of HS Akiskal, M.D.)

In cases of severe bereavement, regardless of diagnosis, some suggest that it would be clinically unwise to withhold antidepressants from many persons experiencing such intense mourning.

COMORBIDITY

Individuals with major depressive disorders are at an increased risk of having one or more additional comorbid disorders. The most frequent disorders are alcohol abuse or dependence, panic disorder, obsessive-compulsive disorder (OCD), and social anxiety disorder. Conversely, individuals with substance use disorders and anxiety disorders also have an elevated risk of lifetime or current comorbid depressive disorders.

Table 7-8
Signs that a Bereaved Person Has Progressed to a Depressive Disorder

Beliefs. Grieving persons and their relatives perceive bereavement as a normal reaction, whereas those with depressive disorder often view themselves as sick and may actually believe they are losing their minds.

Emotional reactivity. Unlike the melancholic person, the grieving person reacts to the environment and tends to show a range of positive effects.

Psychomotor activity. Marked psychomotor retardation is not observed in normal grief.

Guilt. Although bereaved persons often feel guilty about not having done certain things that they believe might have saved the life of the deceased loved one (guilt of omission), they typically do not experience guilt of commission.

Delusions. Delusions of worthlessness or sin and psychotic

experiences in general point toward mood disorder.

Suicidal ideation. Active suicidal ideation is rare in grief but common in major depressive disorder.

Behaviors. "Mummification" (i.e., keeping the belongings of the deceased person exactly as they were before his or her death) indicates serious psychopathology.

Anniversaries. Severe anniversary reactions should alert the clinician to the possibility of psychopathology.

From Akiskal. Mood disorders. In: Sadock BJ, Sadock VA, Ruiz P, eds. *Kaplan & Sadock's Comprehensive Textbook of Psychiatry*. 10th ed. Philadelphia, PA: Wolters Kluwer; 2017.

Anxiety

In anxiety disorders, DSM-5 notes the existence of mixed anxiety–depressive disorder. Significant symptoms of anxiety can and often do coexist with significant symptoms of depression. Whether patients who exhibit significant symptoms of both anxiety and depression are affected by two distinct disease processes or by a single disease process that produces both sets of symptoms are not yet resolved. Patients of both types may constitute a group of patients with mixed anxiety–depressive disorder.

Substance Use Disorder

Alcohol dependence frequently coexists with mood disorders. Both patients with major depressive disorder and those with bipolar I disorder are likely to meet the diagnostic criteria for an alcohol use disorder. The available data indicate that alcohol dependence is more strongly associated with a coexisting diagnosis of depression in women than in men. In contrast, the genetic and family data about men who have both a mood disorder and alcohol dependence indicate that they are likely to have two genetically distinct disease processes.

Substance-related disorders other than alcohol dependence are also commonly associated with mood disorders. The abuse of substances may be involved in precipitating an episode of illness or, conversely, may represent patients' attempts to treat their illnesses. Although manic patients seldom use sedatives to dampen their euphoria, depressed patients often use stimulants,

such as cocaine and amphetamines, to relieve their depression.

Patients with dysthymia commonly meet the diagnostic criteria for a substance-related disorder. This comorbidity can be logical; patients with dysthymia tend to develop coping methods for their chronically depressed state that involve substance abuse. Therefore, they are likely to use alcohol, stimulants such as cocaine, or marijuana, the choice perhaps depending primarily on a patient's social context. The presence of a comorbid diagnosis of substance abuse presents a diagnostic dilemma for clinicians; the long-term use of many substances can result in a symptom picture indistinguishable from that of dysthymia.

Medical Conditions

Depression commonly coexists with medical conditions, especially in older persons. When depression and medical conditions coexist, clinicians must try to determine whether the underlying medical condition is pathophysiologically related to the depression or whether any drugs that the patient is taking for the medical condition are causing the depression. Many studies indicate that the treatment of a coexisting major depressive disorder can improve the course of the underlying medical disorder, including cancer.

COURSE

Studies of the course and prognosis of mood disorders have generally concluded that mood disorders tend to have long courses and that patients tend to have relapses.

Major Depressive Disorder

Onset. About 50 percent of patients having their first episode of major depressive disorder exhibited significant depressive symptoms before the first identified episode. Therefore, early identification and treatment of early symptoms may prevent the development of a full depressive episode. Although symptoms may have been present, patients with major depressive disorder usually have not had a premorbid personality disorder. The first depressive episode occurs before age 40 years in about 50 percent of patients. Later onset is associated with the absence of a family history of mood

disorders, antisocial personality disorder, and alcohol abuse.

Duration. An untreated depressive episode lasts 6 to 13 months; most treated episodes last about 3 months. The withdrawal of antidepressants before 3 months has elapsed almost always results in the return of the symptoms. As the course of the disorder progresses, patients tend to have more frequent episodes that last longer. Over 20 years, the mean number of episodes is five or six.

Other Depressive Disorders

About 50 percent of patients with dysthymia experience an insidious onset of symptoms before age 25 years. Despite the early onset, patients often suffer from the symptoms for a decade before seeking psychiatric help and may consider early-onset dysthymia part of life. Patients with an early onset of symptoms are at risk for either major depressive disorder or bipolar I disorder in the course of their disorder. Studies of patients with the diagnosis of dysthymia indicate that about 20 percent progressed to major depressive disorder, 15 percent to bipolar II disorder, and fewer than 5 percent to bipolar I disorder.

The prognosis for patients with dysthymia varies. Antidepressive agents and specific types of psychotherapies (e.g., cognitive and behavior therapies) have positive effects on the course and prognosis of dysthymia. The available data about previously available treatments indicate that only 10 to 15 percent of patients are in remission 1 year after the initial diagnosis. About 25 percent of all patients with dysthymia never attain complete recovery. Overall, however, the prognosis is good with treatment.

PROGNOSIS

Major depressive disorder is not a benign disorder. It tends to be chronic, and patients tend to relapse. Patients hospitalized for the first episode of major depressive disorder have about a 50 percent chance of recovering in the first year. The percentage of patients recovering after repeated hospitalization decreases with time. Many unrecovered patients remain affected by a dysthymic disorder. About 25 percent of patients have a recurrence in the first 6 months after leaving the hospital. Another 30 to 50 percent recur in the

following 2 years. About 50 to 75 percent of all patients will have a recurrence within 5 years. The incidence of relapse is lower than these figures in patients who continue prophylactic psychopharmacological treatment and in patients who have had only one or two depressive episodes. In general, as a patient experiences more and more depressive episodes, the time between the episodes decreases, and the severity of each episode increases.

Prognostic Indicators

Many studies have focused on identifying both good and bad prognostic indicators in the course of major depressive disorder. Table 7-9 lists some of the positive and negative predictors.

TREATMENT APPROACH

The treatment of mood disorders is rewarding for psychiatrists. Specific treatments are available for depressive episodes, and data indicate that prophylactic treatment is also useful. We should be optimistic, as the prognosis for each episode is excellent. This fact tends to be welcome news for patients and families. Mood disorders are chronic, however, and the psychiatrist must educate the patient and the family about future treatment strategies.

Historically, patients with dysthymia either received no treatment or received long-term, insight-oriented psychotherapy. Contemporary data suggest that the treatments for dysthymia are similar to those for major depressive disorder.

There are several treatment goals. First, the patient's safety must be guaranteed. Second, a complete diagnostic evaluation of the patient is necessary. Third, we should initiate a treatment plan that addresses not only the immediate symptoms but also the patient's prospective well-being. Although current treatment emphasizes pharmacotherapy and psychotherapy addressed to the individual patient, stressful life events increase the chance of relapse. Thus, treatment should address the number and severity of stressors in patients' lives.

Table 7-10 lists the phases of treatment and the typical goals and activities for each phase.

Table 7-9
Prognostic Indicators for Depression

Positive Indicators

Clinical

  Mild severity

  No psychotic symptoms

  Short hospital stay

  No comorbid disease (medical/psychiatric)

  No more than 1 hospitalization

  Advanced age of onset

Psychosocial

  Solid friendships during adolescence

  Stable family functioning

  Good social/occupational functioning in previous 5 yr

Negative Indicators

  Comorbid dysthymic disorder and major depressive disorder

  Substance use disorder

  Anxiety symptoms

  >1 previous episodes

  Male

Hospitalization

The first and most critical decision a physician must make is whether to hospitalize a patient or attempt outpatient treatment. Definite indications for hospitalization are the risk of suicide or homicide, a patient's grossly reduced ability to get food and shelter, and the need for diagnostic procedures. A history of rapidly progressing symptoms and the rupture of a patient's natural support systems are also indications for hospitalization.

A physician may safely treat dysthymia and other forms of milder depression in the office, seeing the patient frequently. Clinical signs of impaired judgment, weight loss, or insomnia should be minimal. The patient's support system should be reliable, neither overinvolved nor

withdrawing from the patient. Any adverse changes in the patient's symptoms or behavior or the attitude of the patient's support system may suffice to warrant hospitalization.

Patients with mood disorders are often unwilling to enter a hospital voluntarily, and we may have to commit them involuntarily. These patients often cannot make decisions because of their slowed thinking, negative *Weltanschauung* (world view), and hopelessness.

Choosing a Treatment

Combined Treatments May Offer the Best Option. We often combine medication and psychotherapy. If physicians view mood disorders as fundamentally evolving from psychodynamic issues, their ambivalence about the use of drugs may result in a poor response, noncompliance, and probably inadequate dosages for too short a treatment period. Alternatively, if physicians ignore the psychosocial needs of a patient, the outcome of pharmacotherapy may be compromised. Several trials of a combination of pharmacotherapy and psychotherapy for chronically depressed outpatients have shown a higher response and higher remission rates for the combination than for either treatment used alone.

Although combination remains the general—and our—recommendation—we should point out that there are other views. Some have argued that most data suggest that single treatment, either psychopharmacological or psychotherapeutic, alone is sufficient for most people, and that combining treatments exposes patients to unnecessary costs and adverse effects.

Somatic Treatments

Pharmacotherapy. The efficacy of pharmacotherapy for major depressive disorder has been well established in more than 500 randomized controlled studies. In general, all available antidepressants show an at least modest effect compared with placebo. Efficacy is broadly similar across agents, at least when compared against placebo. However, tolerability and acceptability vary.

After establishing a diagnosis, we can formulate a pharmacologic treatment strategy. Accurate diagnosis is crucial because unipolar and bipolar spectrum

disorders require different treatment regimens.

The objective of pharmacologic treatment is symptom remission, not just symptom reduction. Patients with residual symptoms, as opposed to full remission, are more likely to experience a relapse or recurrence of mood episodes and to experience ongoing impairment of daily functioning.

The use of specific pharmacotherapy approximately doubles the chances that a depressed patient will recover in 1 month. All currently available antidepressants may take up to 3 to 4 weeks to exert significant therapeutic effects, although they may begin to show their effects earlier. The choice of antidepressants partly depends on the side effect profile that is least objectionable to a given patient's physical status, temperament, and lifestyle. Chapter 21 discusses the many classes of antidepressants. Although most antidepressants seem to have similar mechanisms of action and hence similar efficacy, there are some variations across classes. This variation gives us some diversity of choice. Although the first antidepressant drugs, the monoamine oxidase inhibitors (MAOIs) and tricyclic antidepressants (TCAs), are still in use, newer compounds have made the treatment of depression more "clinician and patient-friendly."

Table 7-10
Phases of Treatment

Treatment Phase	Duration	Goals	Activities
Acute and continuation	8–12 wk	Achieve symptomatic remission Monitor side effects Restore function	Establish therapeutic alliance Provide psychoeducation Select optimal antidepressant treatment(s) Supportive and measurement-based care Monitor progress

| Maintenance | 6–24 mo or longer | Return to full function and quality of life Prevention of recurrence | Continue psychoeducation Rehabilitate Manage comorbidities Monitor for recurrence |

Disease burden and principles of care. *Can J Psychiatry*. 2016;61(9):510–523.

Table 7-11
SSRI and SNRI Antidepressant Medications and Their Side Effect Profiles

Drug Class	Recommended Dose Range (mg)	Side Effect Frequency	
		10–30%	>30%
SSRI			
Citalopram	20–40	Nausea, dry mouth, sweating	None
Escitalopram	10–20	Male sexual dysfunction and nausea	None
Fluoxetine	20–60	Nausea, dry mouth, somnolence, nervousness, anxiety, insomnia, tremor, anorexia	None
Fluvoxamine	100–300	Dry mouth,	Nausea

		headaches, somnolence, agitation, insomnia, sweating, tremor, anorexia, dizziness, constipation	
Paroxetine	20–60	Nausea, diarrhea, dry mouth, headaches, somnolence, insomnia, sweating, asthenia, male sexual dysfunction, dizziness	None
Sertraline	50–200	Nausea, diarrhea, dry mouth, headaches, somnolence, insomnia, fatigue, tremor, male sexual dysfunction, dizziness	None
SNRI			
Venlafaxine	75–375	Headaches, somnolence, dry mouth, dizziness, nervousness, insomnia,	Nausea

		sweating, male sexual dysfunction	
Desvenlafaxine	50–100	Dry mouth, dizziness, nausea, sweating	None
Duloxetine	30–120	Nausea, dry mouth, constipation, insomnia, male sexual dysfunction	None
Levomilnacipran	20–80	Nausea, dry mouth, headaches, male sexual dysfunction	None

Other Second-Generation and Novel Antidepressants

Agomelatine[a]	25–50	None	None
Bupropion	150–450	Insomnia, dry mouth, nausea	Headaches
Mirtazapine	15–60	Dry mouth, constipation, increased appetite, weight gain	Somnolence
Moclobemide[a]	300–600	None	None
Vilazodone	10–40	Diarrhea, nausea, headaches	None
Vortioxetine	10–20	Nausea	None

[a]Not routinely available in the United States.

Table 7-11 lists selective serotonin reuptake inhibitors (SSRIs) and serotonin-norepinephrine reuptake inhibitors (SNRIs) by class as well as their side-effect profiles.

GENERAL CLINICAL GUIDELINES. The most common clinical mistake leading to an unsuccessful trial of an antidepressant drug is the use of too low a dosage for too short a time. Unless adverse events prevent it, the dosage of an antidepressant should be raised to the maximum recommended level and maintained at that level for at least 4 or 5 weeks before a drug trial is considered unsuccessful. Alternatively, if a patient is improving clinically on a low dosage of the drug, this dosage should not be raised unless clinical improvement stops before obtaining a maximal benefit. When a patient does not begin to respond to appropriate dosages of a drug after 2 or 3 weeks, clinicians may decide to obtain a plasma concentration of the drug if such a test is available. The test may indicate either noncompliance or a particularly unusual pharmacokinetic disposition of the drug and may thereby suggest an alternative dosage.

INITIAL MEDICATION SELECTION. The available antidepressants do not differ in overall efficacy, speed of response, or long-term effectiveness. Antidepressants, however, do differ in their pharmacology, drug–drug interactions, short- and long-term side effects, the likelihood of discontinuation symptoms, and ease of dose adjustment. Most often, we start with second- and third-generation antidepressants. Among them, the selective serotonin reuptake inhibitors (SSRIs) remain the most commonly used medications for depression.

Selection of the initial treatment depends on the chronicity of the condition, course of illness (a recurrent or chronic course increases the likelihood of subsequent depressive symptoms without treatment), family

history of illness and treatment response, symptom severity, concurrent general medical or other psychiatric conditions, prior treatment responses to other acute-phase treatments, potential drug–drug interactions, and patient preference.

In general, approximately 45 to 60 percent of all outpatients with uncomplicated (i.e., minimal psychiatric and general medical comorbidity), nonchronic, nonpsychotic major depressive disorder who begin treatment with medication respond (i.e., achieve at least a 50 percent reduction in baseline symptoms); however, only 35 to 50 percent achieve remission (i.e., the virtual absence of depressive symptoms).

DURATION AND PROPHYLAXIS. We should maintain antidepressant treatment for at least 6 months or the length of a previous episode, whichever is greater. When discontinuing antidepressant treatment, the drug dose should be tapered gradually over 1 to 2 weeks, depending on the half-life of the particular compound.

Prophylactic treatment with antidepressants is effective in reducing the number and severity of recurrences. One study concluded that when episodes are less than $2^1/_2$ years apart, we should recommend prophylactic treatment. Another factor suggesting prophylactic treatment is the seriousness of previous depressive episodes. Episodes that have involved significant suicidal ideation or impairment of psychosocial functioning may indicate that the risk of stopping treatment is too considerable.

Prevention of new mood episodes (i.e., recurrences) is the aim of the maintenance phase of treatment. Only patients with recurrent or chronic depressions are candidates for maintenance treatment. Several studies indicate that maintenance antidepressant medication appears to be safe and effective for the treatment of chronic depression.

TREATMENT OF SPECIFIC DEPRESSIVE DISORDERS. Clinical types of major depressive episodes may have varying responses to particular antidepressants or drugs other than antidepressants. Antidepressants with dual action on both serotonergic and noradrenergic receptors may have greater efficacy in melancholic depressions. We can treat patients with seasonal winter depression with light therapy.

Treatment of major depressive episodes with psychotic features may

require a combination of an antidepressant and an atypical antipsychotic. Several studies have also shown that ECT is useful for this indication—perhaps more effective than pharmacotherapy.

For those with atypical symptom features, strong evidence exists for the effectiveness of MAOIs. SSRIs and bupropion are also of use in atypical depression.

COMORBID DISORDERS. The simultaneous presence of another disorder can affect initial treatment selection. For example, the successful treatment of an OCD associated with depressive symptoms usually results in remission of the depression. Similarly, when panic disorder occurs with major depression, medications with demonstrated efficacy in both conditions are preferred (e.g., tricyclics and SSRIs). In general, the nonmood disorder dictates the choice of treatment in comorbid states.

Concurrent substance abuse raises the possibility of a substance-induced mood disorder, which must be evaluated by history or by requiring abstinence for several weeks. Abstinence often results in remission of depressive symptoms in substance-induced mood disorders. For those with continuing significant depressive symptoms, even with abstinence, an independent mood disorder is diagnosed and treated.

General medical conditions are established risk factors in the development of depression. The presence of a major depressive episode is associated with increased morbidity or mortality of many general medical conditions (e.g., cardiovascular disease, diabetes, cerebrovascular disease, and cancer).

THERAPEUTIC USE OF SIDE EFFECTS. Choosing more sedating antidepressants (such as mirtazapine or paroxetine) for more anxious, depressed patients or more activating agents (bupropion) for more psychomotor-retarded patients is not as helpful as one might think. For example, any short-term benefits with paroxetine or mirtazapine on symptoms of anxiety or insomnia may become liabilities over time. These drugs often continue to be sedating in the longer run, which can lead to patients prematurely discontinuing medication and increase the risk of relapse or recurrence. Some practitioners use adjunctive medications, such as hypnotics or anxiolytics, combined with antidepressants to provide more immediate symptom relief or to cover those side effects to which most patients ultimately adapt.

Understanding a patient's prior treatment history is essential because an earlier response typically predicts future responses. A documented failure on a properly conducted trial of a particular antidepressant class is grounds to choose an agent from an alternative class. The history of a first-degree relative responding to a particular drug is associated with a positive response to the same class of agents in the patient.

ACUTE TREATMENT FAILURES. Patients may not respond to medication, because (1) they cannot tolerate the side effects, even in the face of an excellent clinical response; (2) an idiosyncratic adverse event may occur; (3) the clinical response is not adequate; or (4) the wrong diagnosis has been made. Acute phase medication trials should last 4 to 6 weeks to allow for adequate time for meaningful symptom reduction. Most (but not all) patients who ultimately respond fully show at least a partial response by the fourth week, assuming an adequate dose. A "partial response" is defined as at least a 20 to 25 percent reduction in pretreatment depressive symptom severity. Patients who have not even a partial response in that time likely need a change of treatment. More extended periods—8 to 12 weeks or longer—are needed to define the ultimate degree of symptom reduction achievable with a medication. Approximately half of patients require a second medication treatment trial because the initial treatment is poorly tolerated or ineffective.

Selecting Second Treatment Options. When the initial treatment is unsuccessful, switching to an alternative treatment or augmenting the current treatment is a standard option. The choice between switching from the single initial treatment to a new single treatment (as opposed to adding a second treatment to the first one) rests on the patient's prior treatment history, the degree of benefit achieved with the initial treatment, and patient preference. As a rule, switching rather than augmenting is preferred after an initial medication failure. On the other hand, augmentation strategies are helpful with patients who have gained some benefit from the initial treatment but who have not achieved remission. A review of the different strategies suggested there is some evidence suggesting that both strategies do confer some benefit. However, the evidence is inadequate to suggest one strategy over another.

When switching from one monotherapy to another, the usual suggestion is

to pick a medication in a different class. For example, we might switch from an SSRI to an SNRI. However, when putting these assumptions to the test, it is difficult to find any advantage for any particular strategy. For example, in the landmark STAR*D study, which remains one of the most extensive studies of treatment strategies following initial failure, although medication switches were modestly helpful, both switches within and outside a class were equally effective.

Among augmentation options, several approaches have reasonable evidence. Several antipsychotics, most notably quetiapine and aripiprazole, are effective for augmentation. Lithium augmentation is also effective for augmenting both SSRIs and TCAs. There are also positive studies of thyroid hormone. However, this strategy is rarely used in clinical practice owing to the need for ongoing monitoring and potential adverse effects. Several other agents have been studied, including bupropion, buspirone, lamotrigine, methylphenidate, and pindolol; however, these have limited placebo-controlled data. One meta-analysis of the available data on switching strategies concluded that quetiapine and aripiprazole have the best evidence as augmentation agents. However, we should use these cautiously given their side effect profile.

NOVEL PHARMACOLOGIC AGENTS

Ketamine. The anesthetic agent ketamine is effective in treatment-resistant depression. It has a mechanism of action that inhibits the postsynaptic glutamate-binding protein N-methyl-D-aspartate (NMDA) receptor. Because abnormalities in glutamatergic signaling seem to have a role in major depressive disorder, this may account for its efficacy. Until recently, ketamine was only available intravenously, limiting its use as we had to monitor patients while they received an infusion of the drug over 30 minutes in a clinical setting. The most common side effects are dizziness, headache, and poor coordination, which are transitory. Dissociative symptoms, including hallucinations, may also occur. A positive response is usually seen within 24 hours, making this a genuinely novel substance in that it appears to act much more rapidly than standard antidepressants. However, the effect seems to be short-lived, and wears off after between 2 and 7 days, again limiting its use. There are little data on longer-term treatment as well as concern over associated adverse effects, particularly the psychogenic effect.

Also, the agent has an abuse potential, making it less attractive as a long-term option.

More recently, esketamine in a nasal spray formulation was approved by the FDA for treatment-resistant depression. Given the abuse risk, it is only available through a restricted distribution system. Most of the supportive evidence for the agent is from short-term use. However, one longer-term study suggested that continuation treatment could be effective for some patients.

Brexanolone. Brexanolone is an intravenous formulation of allopregnanolone, which was approved by the FDA in 2019 for the treatment of postpartum depression. It is a neuroactive steroid that also has a neuroactive effect, functioning as an allosteric modulator of GABA$_A$, *which may be central to the mechanism of postpartum depression. It is also only available in the United States through a restricted program that requires administrating the drug in a clinical setting over 60 hours. The most common adverse effects are sleepiness, dry mouth, loss of consciousness, and flushing. As with ketamine, brexanolone differs from standard antidepressants in its apparent rapid effect, reducing depressive symptoms as early as 24 hours after administration. In trials, the effect continued for at least 30 days. As of this writing, phase 3 trials for an oral version of the medication have promising results.*

Other Somatic Treatments

NEUROSTIMULATION

Vagal Nerve Stimulation. Experimental stimulation of the vagus nerve in several studies designed for the treatment of epilepsy found that patients showed improved mood. This observation led to the use of left vagal nerve stimulation (VNS) using an electronic device implanted in the skin, similar to a cardiac pacemaker. Preliminary studies have shown that many patients with chronic, recurrent major depressive disorder went into remission when treated with VNS. The mechanism of action of VNS to account for improvement is unknown. The vagus nerve connects to the enteric nervous system and, when stimulated, may cause the release of peptides that act as neurotransmitters.

Transcranial Magnetic Stimulation. Transcranial magnetic stimulation (TMS) shows promise as a treatment for depression. It involves the use of very short pulses of magnetic energy to stimulate nerve cells in the brain. The FDA has indicated this treatment for depression in adult patients who have failed to achieve satisfactory improvement from one prior antidepressant medication at or above the minimal effective dose and duration in the current episode.

Repetitive transcranial magnetic stimulation (rTMS) produces focal secondary electrical stimulation of targeted cortical regions. It is nonconvulsive, requires no anesthesia, has a safe side effect profile, and is not associated with cognitive side effects.

The patients do not require anesthesia or sedation and remain awake and alert. It is a 40-minute outpatient procedure that is prescribed by a psychiatrist and performed in a psychiatrist's office. The treatment is typically administered daily for 4 to 6 weeks. The most common adverse event related to treatment was scalp pain or discomfort.

TMS therapy is contraindicated in patients with implanted metallic devices or nonremovable metallic objects in or around the head.

PHOTOTHERAPY. Phototherapy (light therapy) was introduced in 1984 as a treatment for SAD (mood disorder with seasonal pattern). In this disorder, patients typically experience depression as the photoperiod of the day decreases with advancing winter. Women represent at least 75 percent of all patients with seasonal depression, and the mean age of presentation is 40 years. Patients rarely present older than the age of 55 years with SAD.

Phototherapy typically involves exposing the affected patient to bright light in the range of 1,500 to 10,000 lux or more, typically with a lightbox that sits on a table or desk. Patients sit in front of the box for approximately 1 to 2 hours before dawn each day. Some patients may also benefit from exposure after dusk. Alternatively, some manufacturers have developed light visors, with a light source built into the brim of the hat. These light visors allow mobility, but recent controlled studies have questioned the use of this type of light exposure. Trials have typically lasted 1 week, but longer treatment durations may be associated with a more significant response.

Phototherapy is usually well tolerated. Newer light sources tend to use lower light intensities and come equipped with filters; patients are instructed

not to look directly at the light source. As with any effective antidepressant, phototherapy, on rare occasions, has been implicated in switching some depressed patients into mania or hypomania.

In addition to seasonal depression, the other significant indication for phototherapy may be in sleep disorders. Phototherapy can decrease the irritability and diminished functioning associated with shift work. Sleep disorders in geriatric patients have reportedly improved with exposure to bright light during the day. Likewise, some evidence suggests that jet lag might respond to light therapy. Preliminary data indicate that phototherapy may benefit some patients with OCD that has a seasonal variation.

SLEEP DEPRIVATION. Sleep disturbances are common in depression. Depression can be associated with either hypersomnia or insomnia. Sleep deprivation may temporarily relieve depression in those who have unipolar depression. Approximately 60 percent of patients with depressive disorders exhibit significant but transient benefits from total sleep deprivation. The positive results usually reverse by the next night of sleep. Several strategies have been used in an attempt to achieve a more sustained response to sleep deprivation. One method used serial total sleep deprivation with a day or two of normal sleep in between. This method does not achieve a sustained antidepressant response because the depression tends to return during the "normal sleep" days. Another approach used phase delay in the time patients go to sleep each night, or partial sleep deprivation. In this method, patients may stay awake from 2 AM to 10 PM daily. Up to 50 percent of patients get same-day antidepressant effects from partial sleep deprivation, but this benefit also tends to wear off in time. In some reports, however, serial partial sleep deprivation has been used successfully to treat insomnia associated with depression. The third, and probably most useful strategy combines sleep deprivation with pharmacologic treatment of depression. Several studies have suggested that total and partial sleep deprivation followed by immediate treatment with an antidepressant or lithium sustains the antidepressant effects of sleep deprivation. Likewise, several reports have suggested that sleep deprivation accelerates the response to antidepressants. Sleep deprivation may also improve premenstrual dysphoria.

Table 7-12

Evidence-Based Psychotherapies for Major Depressive Disorder

Treatment	Conceptualization of Disorder Etiology	Sample Interventions
Behavioral therapy	Deficit of reinforcers, including pleasant activities and positive interpersonal contacts	Increase activity level Structured goal setting Interpersonal skills training
Cognitive-behavioral therapy	Interaction of beliefs with matching stressor	Identify and challenge automatic thoughts Engage in activities that provide evidence disproving dysfunctional beliefs Modify core beliefs by reviewing evidence
Interpersonal psychotherapy	Interpersonal vulnerabilities arising from early attachment and learned relationship patterns	Develop awareness of patterns in primary relationships and the therapeutic relationship Interpersonal skills training Communication analysis
Behavioral marital	Marital distress increases stress	Assertive communication

therapy	while impairing support resources	training
		Active listening exercises
		Problem-solving skills
		Increasing reinforcing behaviors toward spouse

Psychosocial Therapy

Three types of short-term psychotherapies—cognitive therapy, interpersonal therapy, and behavior therapy—have extensive studies for the treatment of major depressive disorder. In addition to these individual therapies, there are positive studies for behavioral marital therapy as well. Table 7-12 lists the evidence-based psychotherapies for major depressive disorder.

There are no generally accepted guidelines for choosing one therapy over another. The National Institute of Mental Health (NIMH) Treatment of Depression Collaborative Research Program did find some possible predictors of good response to specific treatments. Table 7-13 summarizes those findings.

Cognitive Therapy. Cognitive therapy, originally developed by Aaron Beck, focuses on the cognitive distortions postulated to be present in major depressive disorder. Such distortions include selective attention to the negative aspects of circumstances and unrealistically morbid inferences about consequences. For example, apathy and low energy result from a patient's expectation of failure in all areas. The goal of cognitive therapy is to alleviate depressive episodes and prevent their recurrence by helping patients identify and test negative cognitions; develop alternative, flexible, and positive ways of thinking; and rehearse new cognitive and behavioral responses.

In this example, the therapist takes a cognitive approach when a patient shows up late to an appointment.

Therapist: You mentioned that you were upset because you were late. Can you tell me what you were thinking when you realized you were late?

Patient: I figured you'd be angry.

Therapist: Okay, and when you thought I'd be angry, how did you feel?

Patient: Pretty nervous.

Therapist: So that is what we will focus on in here, how your thinking in different situations influences how you feel. In this case, you were late, thought "he'll be angry," and felt nervous. Our goal is to test out the beliefs, like "he'll be angry," and change them when they aren't healthy or accurate. The great thing is that you sort of implicitly tested out the belief that I'll be angry by showing up. Was I angry?

Patient: You didn't seem angry.

Table 7-13
Predictors of Response to Several Therapies for Depression

Treatment	Predictors
Interpersonal psychotherapy	Low social dysfunction High depression severity
Cognitive-behavioral therapy	Low cognitive dysfunction
Pharmacotherapy	Low cognitive dysfunction High depression severity High work dysfunction

Data from Sotsky SM, Glass DR, Shea MT, Pilkonis PA, Collins JF, Elkin I, Watkins JT, Imber SD, Leber WR, Moyer J, Oliveri ME. Patient predictors of response to psychotherapy and pharmacotherapy: findings in the NIMH Treatment of Depression Collaborative Research Program. *Am J Psychiatry*. 1991;148:997–1108.

Therapist: How anxious did you feel once we started talking?

Patient: Well, I'm feeling more comfortable.

Therapist: What thoughts do you have now about me being angry?

> Patient: I don't think you're angry.
>
> Therapist: So, this is an example of what we're going to be doing in therapy—I'll be helping you to identify thoughts that make you feel bad. We're then going to work together to come up with ways to check them out and change them if they're not true or accurate. You checked out whether I was angry by observing me, and you changed your thought, and, now, I get the impression that you feel better.

Studies have shown that cognitive therapy is useful in the treatment of major depressive disorder. Most studies found that cognitive therapy is equal in efficacy to pharmacotherapy and is associated with fewer adverse effects and better follow-up than pharmacotherapy. Some of the best-controlled studies have indicated that the combination of cognitive therapy and pharmacotherapy is more efficacious than either therapy alone, although other studies have not found that additive effect.

Interpersonal Therapy. Interpersonal therapy, developed by Gerald Klerman, focuses on one or two of a patient's current interpersonal problems. This therapy has two assumptions. First, current interpersonal problems are likely to have their roots in early dysfunctional relationships. Second, current interpersonal problems are likely to be involved in precipitating or perpetuating the current depressive symptoms. Controlled trials have indicated that interpersonal therapy is effective for treatment of major depressive disorder and, not surprisingly, may be specifically helpful in addressing interpersonal problems. Some studies indicate that interpersonal therapy may be the most effective method for severe major depressive episodes when the treatment choice is psychotherapy alone.

The interpersonal therapy program usually consists of 12 to 16 weekly sessions and is characterized by an active therapeutic approach. Intrapsychic phenomena, such as defense mechanisms and internal conflicts, are not addressed. Discrete behaviors—such as lack of assertiveness, impaired social skills, and distorted thinking—may be addressed but only in the context of their meaning in, or their effect on, interpersonal relationships.

Behavior Therapy. Behavior therapy rests on the hypothesis that

maladaptive behavioral patterns result in a person's receiving little positive feedback and perhaps outright rejection from society. By addressing maladaptive behaviors in therapy, patients learn to function in the world in such a way that they receive positive reinforcement. Behavior therapy for major depressive disorder has not yet been the subject of many controlled studies. The limited data indicate that it is an effective treatment for major depressive disorder.

Psychoanalytically Oriented Therapy. Although not as well researched as those three therapies, many clinicians use psychoanalytically oriented psychotherapy as their primary method. What differentiates the short-term psychotherapy methods from the psychoanalytically oriented approach are the active and directive roles of the therapist, the directly recognizable goals, and the endpoints for short-term therapy.

The psychoanalytic approach to mood disorders uses psychoanalytic theories about depression. The goal of psychoanalytic psychotherapy is to effect a change in a patient's personality structure or character, not merely to alleviate symptoms. Improvements in interpersonal trust, capacity for intimacy, coping mechanisms, the capacity to grieve, and the ability to experience a wide range of emotions are some of the aims of psychoanalytic therapy. Treatment often requires the patient to experience periods of heightened anxiety and distress during therapy, which may continue for several years.

Accumulating evidence is encouraging about the efficacy of dynamic therapy. In a randomized, controlled trial comparing psychodynamic therapy with cognitive-behavioral therapy, the outcome of the depressed patients was the same in the two treatments.

Family Therapy. Family therapy is usually the first-line treatment for major depressive disorder, but increasing evidence indicates that helping a patient with a mood disorder to reduce and cope with stress can lessen the chance of a relapse. We should consider family therapy if the disorder jeopardizes a patient's marriage or family functioning or if the mood disorder is promoted or maintained by the family situation. Family therapy examines the role of the mood-disordered member in the overall psychological well-being of the whole family; it also examines the role of the entire family in the

maintenance of the patient's symptoms. Patients with mood disorders have a high rate of divorce, and about 50 percent of all spouses report that they would not have married or had children if they had known that the patient was going to develop a mood disorder.

THE EPIDEMIOLOGY OF DEPRESSION

Research on the epidemiology of depression, both in the United States and worldwide, has considerably broadened our understanding of the disorder. We have discovered that depression is much more common than once thought. It is also one of the more debilitating disorders known to humanity, as it often affects individuals during what should be their most productive years. Hence the depressive disorders are one of the most costly disorders in society.

Measuring the Incidence and Prevalence of Major Depressive Disorder Is Challenging

Measuring the true incidence of major depressive disorder is complicated and highly dependent on the methods used to collect the sample, definitions of the disorder, and the particular instruments used to measure depression. For example, studies that use self-assessment tend to report higher incidences than studies using clinician-rated instruments. The timing of a study likely affects the results as well. As depressive illness become less stigmatized, persons may be more willing to endorse symptoms of the disorder to the well-meaning strangers who knock at their door, call their phone, or email them and identify themselves as researchers.

Incidence and Prevalence

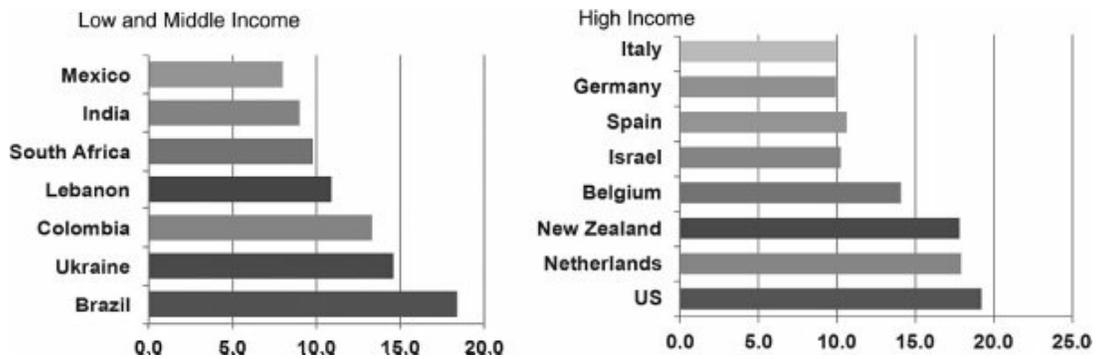
In a reasonably recent meta-analysis, which included 90 studies from 30 countries done from 1994 to 2014, with combined data on more than 1 million participants, the point prevalence for depression was 12.9 percent, the 1-year prevalence was 7.2 percent, and the lifetime prevalence was 10.8 percent. There was significant heterogeneity among the different studies.


FIGURE 7-1
Lifetime prevalence of major depression across the world.

In the United States, the most recent epidemiologic data is from the National Survey on Drug Use and Health (NSDUH), sponsored by the Substance Abuse and Mental Health Services Administration (SAMHSA). Using a definition of a major depressive episode based on DSM-5, they found the overall 1-year prevalence of a major depressive episode to be 7.1 percent, hence very similar to the international data. Figure 7-1 summarizes some of the international prevalence data as it related to per capita income.

Sex

An almost universal observation, independent of country or culture, is that depression is more common in women than men. In the international meta-analysis, the aggregate prevalence for women was 14.4 percent versus 11.5 percent in men. In the United States, women were more likely to report a major depressive episode in the past year (8.7 percent) than men (5.3 percent).

There are various possible explanations, both biologic, psychological, and social, for this difference. A women's unequal status in many societies may make women more vulnerable to depression. Although this remains a valid hypothesis, it is notable that in societies where women have gained a better level of status, such as many Western societies, the ratio has not significantly changed. Although the explanation is undoubtedly complex and multifactorial, the weight of existing evidence suggests that biologic differences between men and women, such as variations in hormonal levels, do account for at least part of this difference.

Age

The mean age of onset for major depressive disorder is about 40 years, with 50 percent of all patients having an onset between the ages of 20 and 50 years. Major depressive disorder can also begin in childhood or old age. Some epidemiologic data suggest that the incidence of major depressive disorder may be increasing among younger persons. For example, in the SAMHSA study, major depressive disorder was almost twice as prevalent in adolescents as it was in adults, the most substantial difference being seen in adolescent females who reported a 1-year prevalence of major depression of 20 percent. The highest 1-year prevalence for major depressive disorder was in younger adults (adults ages 18 to 25).

Marital Status

Major depressive disorder occurs most often in persons without close interpersonal relationships and in those who are divorced or separated.

Socioeconomic and Cultural Factors

There is no proven correlation between socioeconomic status and major depressive disorder. Depression may be more common in rural areas than in urban areas. However, the most recent international meta-analysis described above did not find such a difference. It may be that technology and globalization have been able to narrow the differences between rural and urban settings.

Racial and ethnic differences may be particularly challenging to measure and may be highly dependent on method, approach, and locale. In the SAMSHA study, the highest prevalence was seen in White and Native American respondents.

THE NEUROBIOLOGY OF DEPRESSION

Since the time of Kraepelin, researchers have examined the brains, bodies, and behaviors of depressed patients in the search for clues of the underlying pathology of depression. This search is complicated by the fact that most experts on depression agree what we call major depressive disorder is not a single disease, but rather a collection of disorders with overlapping phenomenology but different etiologies and pathologies. Although this

assumption seems likely, we have yet to find definitive subtypes or distinct patterns that we can confidently group into separate disorders. This area of research is a rapidly changing field, and improvements in technology, including higher-resolution imaging, more efficient genotyping, and more powerful computing power are getting us closer to the search for valid "biotypes" of depression.

What follows here are examples of pathologic findings, most of which have been reasonably replicated by different investigators. Some are long known, others are recent. However, the growing collection of pathologic findings is helping us to understand what is happening when a patient says that they are "depressed."

Depression as a Disorder of Homeostasis

Depression and the Hypothalamic–Pituitary–Adrenal Axis. We have known for more than 50 years that, on average, depressed patients have an overactive hypothalamic–pituitary–adrenal (HPA) axis. Compared with controls, depressed patients have increased cortisol levels over 24 hours. We have documented elevated HPA activity in depression via excretion of urinary-free cortisol (UFC), 24-hour (or shorter time segments) intravenous (IV) collections of plasma cortisol levels, salivary cortisol levels, and tests of the integrity of feedback inhibition. Evidence of increased HPA activity is apparent in 20 to 40 percent of depressed outpatients and 40 to 60 percent of depressed inpatients.

This hypercortisolemia is due to increased corticotropin-releasing hormone (CRH) from the hypothalamus, along with decreased feedback inhibition. We can test for a disturbance of feedback inhibition using the dexamethasone test (DST). The DST was devised in the 1980s—patients were given dexamethasone—a synthetic steroid. This should create a negative feedback loop, and serum cortisol should decrease. However, depressed patients show an initial decrease but then "escape" from the suppression and return to abnormally high levels of cortisol. Although this is a replicable finding, it is not useful enough to be a diagnostic test, as it is neither sensitive (many patients diagnosed with depression have a normal DST) nor specific (many other conditions, such as Cushing syndrome, or simple environmental stress, can cause an abnormal DST).

Postmortem studies have shown increased neurons in the hypothalamus, which is likely what is driving the increased activity. This neuronal increase is likely in response to chronic stress.

Elevated HPA activity is a hallmark of the mammalian stress responses and one of the most unambiguous links between depression and the biology of chronic stress. Hypercortisolema in depression suggests one or more of the following central disturbances: decreased inhibitory serotonin tone, increased drive from norepinephrine, acetylcholine (ACh), or CRH; or decreased feedback inhibition from the hippocampus. Some studies in depressed humans indicate that a history of early trauma is associated with increased HPA activity accompanied by structural changes (i.e., atrophy or decreased volume) in the cerebral cortex.

DEPRESSION ALSO AFFECTS OTHER ENDOCRINE AND RELATED REGULATORY SYSTEMS

Thyroid Axis Activity. Approximately 5 to 10 percent of people evaluated for depression have previously undetected thyroid dysfunction, as reflected by an elevated basal thyroid-stimulating hormone (TSH) level or an increased TSH response to a 500-mg infusion of the hypothalamic neuropeptide thyroid-releasing hormone (TRH). Such abnormalities are often associated with elevated antithyroid antibody levels and, unless corrected with hormone replacement therapy, can compromise response to treatment. An even more significant subgroup of depressed patients (e.g., 20 to 30 percent) shows a blunted TSH response to TRH challenge. To date, the major therapeutic implication of a blunted TSH response is evidence of an increased risk of relapse despite preventive antidepressant therapy. Of note, unlike the dexamethasone-suppression test (DST), blunted TSH response to TRH does not usually normalize with effective treatment.

Growth Hormone. Growth hormone (GH) is secreted from the anterior pituitary after stimulation by NE and dopamine. Somatostatin, a hypothalamic neuropeptide, and CRH inhibit this secretion. Decreased CSF somatostatin levels occur in depression, as do increased levels in mania.

Prolactin. Prolactin is released from the pituitary by serotonin stimulation and inhibited by dopamine. Most studies have not found significant

abnormalities of basal or circadian prolactin secretion in depression, although some see a blunted prolactin response to various serotonin agonists. This response is uncommon among premenopausal women, suggesting that estrogen has a moderating effect.

Brain-Derived Neurotrophic Factor. Various growth factor proteins, of which brain-derived neurotrophic factor (or BDNF) is best understood, are responsible for the ongoing maintenance of neurons in the brain, and disruption of it causes a reduction in neuronal number and size. It is challenging to measure BDNF in the living subjects, but postmortem studies have suggested deficits in BDNF may correlate with psychopathology. For example, some studies have found that in postmortem examination of persons who died from suicide, the average BDNF in the prefrontal cortex (PFC) and hippocampus was lower than for control subjects. Indirect studies in live patients, looking at BDNF in plasma rather than the brain (the correlation between the two is not clear), found increases in serum BDNF in depressed patients who responded to antidepressants.

BDNF may provide clues to the relationship between chronic stress and depression as the activity of the gene coding for this growth factor decreases with chronic stress, as does neurogenesis.

Similarly, animal studies show that a variety of factors, including antidepressants, estrogen, lithium, and neurostimulation, all increase BDNF in the brain, suggesting a possible common link between known treatments for depression.

DEPRESSION ALSO DISRUPTS CIRCADIAN RHYTHM. It has also long been known that depression is associated with a premature loss of deep (slow-wave) sleep and an increase in nocturnal arousal. Four types of disturbance reflect the latter: (1) an increase in nocturnal awakenings, (2) a reduction in total sleep time, (3) increased phasic rapid eye movement (REM) sleep, and (4) increased core body temperature. The combination of increased REM drive and decreased slow-wave sleep results in a significant reduction in the first period of non-REM (NREM) sleep, a phenomenon referred to as *reduced REM latency*. Blunted secretion of GH may cause this reduction in latency, which usually increases with sleep onset. It is very persistent, often lasting beyond recovery from depression. Some patients manifesting a

characteristically abnormal sleep profile are known to be less responsive to psychotherapy and to have a higher risk of relapse or recurrence and may benefit preferentially from pharmacotherapy.

As with the HPA access, the association between sleep disturbances and depression is common, but it is neither sensitive nor specific enough for clinical use. About 40 percent of outpatients and 80 percent of inpatients show a typical pattern of reduced REM latency, increased REM density, and decreased sleep maintenance. False-negative findings are common in younger, hypersomnolent patients, who may experience an increase in slow-wave sleep during episodes of depression. Approximately 10 percent of otherwise healthy individuals have abnormal sleep profiles, as do many patients suffering from other medical or psychiatric disorders.

Neurotransmitter Deficits Are Involved. Much of the research into the neurobiology of depression has centered on the role played by neurotransmitters. This approach was understandable, given that most somatic treatments for depression appear to act by influencing neurotransmission. In the 1950s, researchers found that reserpine, an antihypertensive that acts by inhibiting the release of monoamine neurotransmitters, sometimes induced depression. During the same decade, others discovered the earliest antidepressants. Although the discoveries were serendipitous, it eventually became clear that they all interfered with the catabolism of monoamine neurotransmitters, and researchers presumed that this must be their mechanism of action. It was reasonable, then, to assume that depression was due to abnormally low levels of these monoamines. Early theories of depression explained the disorder as a deficit or imbalance in neurotransmitters: hence depressed patients were often told that they had a "chemical imbalance." Such a simplistic theory was, of course, overly optimistic, and subsequent neurochemical research did not find such simple relationships. However, neurotransmitters do play an essential role in the disorder, and subsequent findings have helped to clarify this role.

NOREPINEPHRINE. Perhaps the most compelling evidence for the central role of the noradrenergic system in depression is the well-replicated finding that antidepressant response is correlated with the downregulation or decreased sensitivity of β-adrenergic receptors. Also, presynaptic $β_2$-receptors appear to

have a role, as activation of these receptors results in a decrease in the amount of norepinephrine released. Presynaptic β_2-receptors are also located on serotonergic neurons and regulate the amount of serotonin released.

SEROTONIN. Most modern antidepressants act on serotonin, rather than norepinephrine, and as a result, serotonin has become the biogenic amine neurotransmitter most commonly associated with depression. The identification of multiple serotonin receptor subtypes has also increased the excitement within the research community about the development of even more specific treatments for depression. Besides treatment studies, other data indicate that serotonin is involved in the pathophysiology of depression. Depletion of serotonin may precipitate depression, and some patients with suicidal impulses have low cerebrospinal fluid (CSF) concentrations of serotonin metabolites and low concentrations of serotonin uptake sites on platelets.

DOPAMINE. Although norepinephrine and serotonin are the biogenic amines most often associated with the pathophysiology of depression, dopamine may also play a role. Dopamine activity may be reduced in depression and increased in mania. The discovery of new subtypes of the dopamine receptors and an increased understanding of the presynaptic and postsynaptic regulation of dopamine function have further enriched research into the relationship between dopamine and mood disorders. Drugs that reduce dopamine concentrations, including the reserpine mentioned above, as well as diseases that deplete dopamine such as Parkinson disease, all may cause depressive symptoms. In contrast, drugs that increase dopamine concentrations, such as tyrosine, amphetamine, and bupropion, reduce the symptoms of depression.

OTHER NEUROTRANSMITTER DISTURBANCES. Acetylcholine (ACh) is found in neurons that are distributed diffusely throughout the cerebral cortex. Cholinergic neurons have reciprocal or interactive relationships with all three monoamine systems. Abnormal levels of choline, which is a precursor to ACh, have been found at autopsy in the brains of some depressed patients. Cholinergic agonists can cause symptoms of lethargy, anergia, and psychomotor retardation. In an animal model of depression, strains of mice

that are super- or subsensitive to cholinergic agonists have been found susceptible or more resistant to animal models of depression. Cholinergic agonists can induce changes in HPA activity and sleep that mimic those associated with severe depression. Some patients with mood disorders in remission, as well as their never-ill first-degree relatives, have a trait-like increase in sensitivity to cholinergic agonists.

γ-Aminobutyric acid (GABA) has an inhibitory effect on ascending monoamine pathways, particularly the mesocortical and mesolimbic systems. Reductions of GABA occur in plasma, CSF, and brain GABA levels in depression. Animal studies have also found that chronic stress can reduce and eventually can deplete GABA levels. By contrast, antidepressants upregulate GABA receptors, and some GABAergic medications have weak antidepressant effects.

The amino acids glutamate and glycine are the primary excitatory and inhibitory neurotransmitters in the CNS. Glutamate and glycine bind to sites associated with the NMDA receptor and an excess of glutamatergic stimulation can cause neurotoxic effects. Importantly, a high concentration of NMDA receptors exists in the hippocampus. Glutamate, thus, may work in conjunction with hypercortisolemia to mediate the deleterious neurocognitive effects of severe recurrent depression. Emerging evidence suggests that drugs that antagonize NMDA receptors have antidepressant effects.

SECOND MESSENGERS AND INTRACELLULAR CASCADES. The binding of a neurotransmitter and a postsynaptic receptor triggers a cascade of membrane-bound and intracellular processes mediated by second messenger systems. Second messengers regulate the function of neuronal membrane ion channels. Increasing evidence also indicates that mood-stabilizing drugs act on these second messengers.

Immunologic Disturbance. Depressive disorders are associated with several immunologic abnormalities, including decreased lymphocyte proliferation in response to mitogens and other forms of impaired cellular immunity. These lymphocytes produce neuromodulators, such as corticotropin-releasing factor (CRF), and cytokines, peptides known as interleukins. There appears to be an association with clinical severity, hypercortisolism, and immune dysfunction, and the cytokine interleukin-1

may induce gene activity for glucocorticoid synthesis.

Findings from Brain Imaging

STRUCTURAL IMAGING. The most consistent abnormality observed in depressive disorders is the increased frequency of abnormal hyperintensities in subcortical regions, such as periventricular regions, the basal ganglia, and the thalamus. More common among elderly adults, these hyperintensities appear to reflect the deleterious neurodegenerative effects of recurrent affective episodes. Ventricular enlargement, cortical atrophy, and sulcal widening also have been reported in some studies. Some depressed patients also may have reduced hippocampal or caudate nucleus volumes, or both, suggesting more focal defects in relevant neurobehavioral systems. Diffuse and focal areas of atrophy are associated with increased illness severity, bipolarity, and increased cortisol levels.

Also, specific structures appear reduced in volume in patients with depression, for example, the hippocampus. This reduction may be due to neuronal loss due to the neurotoxic effects of the increased cortisol found in depressed patients. Although many areas of the brain are susceptible to this toxic effect, the hippocampus is particularly vulnerable, as it is rich in glutaminergic neurons. Other areas with reported brain loss include the PFC, cingulate gyrus, and cerebellum.

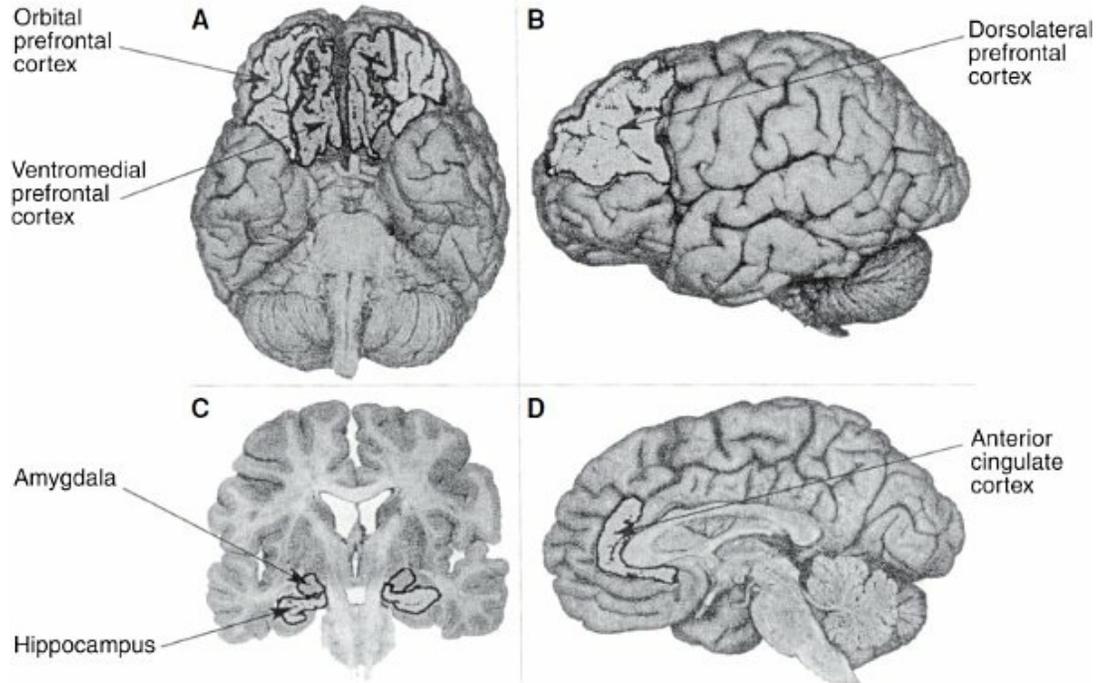
FUNCTIONAL IMAGINING. The most widely replicated positron emission tomography (PET) finding in depression is decreased anterior brain metabolism, which is generally more pronounced on the left side. From a different vantage point, depression may cause a relative increase in nondominant hemispheric activity. Furthermore, a reversal of hypofrontality occurs after shifts from depression into hypomania, such that higher left hemisphere reductions occur in depression compared with more significant right hemisphere reductions in mania. Other studies have observed more specific reductions of reduced cerebral blood flow or metabolism, or both, in the dopaminergically innervated tracts of the mesocortical and mesolimbic systems in depression. Evidence suggests that antidepressants at least partially normalize these changes.


FIGURE 7-2
Key brain regions involved in affect and mood disorders. **A:** Orbital prefrontal cortex and the ventromedial prefrontal cortex. **B:** Dorsolateral prefrontal cortex. **C:** Hippocampus an¨d amygdala. **D:** Anterior cingulate cortex. (From Thase ME. Mood disorders neurobiology. In: Sadock BJ, Sadock VA, Ruiz P. (eds.). *Kaplan & Sadock's Comprehensive Textbook of Psychiatry*. 10th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2017.)

In addition to a global reduction of anterior cerebral metabolism, increased glucose metabolism occurs in several limbic regions, particularly among patients with relatively severe recurrent depression and a family history of mood disorder. During episodes of depression, increased glucose metabolism correlates with intrusive ruminations.

One meta-analysis found three consistent differences when comparing fMRI studies of depressed patients with healthy controls. They found activation of the pulvinar nucleus of the thalamus, more significant response to negative stimuli in the amygdala, insula and anterior cingulate, and lesser response in the dorsal striatum and dorsal lateral PFC.

Figure 7-2 illustrates some of the brain regions thought to be most critical to mood regulation.

Our Understanding of the Genetics of Depressive Disorders

Numerous family, adoption, and twin studies have long documented the heritability of mood disorders. Recently, however, the primary focus of genetic studies has been to identify specific susceptibility genes using molecular genetic methods.

Studies of Inheritance Patterns. Depression aggregates within families and meta-analytic studies suggest that first-degree relatives of persons with major depressive disorder have an increased odds ratio of 2.84 for developing the disease. Only limited adoption studies have been done, of varying quality and with mixed results, and most of what we know about the genetic contribution to the disorder comes from twin studies, which estimate the heritability to be 37 percent. It appears that this heritability is higher in women. The twin studies also concluded that shared environmental factors did not play a significant role in the familial aggregation of the disorder.

Genetic Studies. Genome-wide association studies have not found significant associations. Although there are various explanations for the lack of replicated findings, it likely relates to the fact that GWAS is powered to detect common variants, and that the genes relevant to depression risk are rare.

Candidate gene studies, which instead focus on specific genes of interest, have resulted in many reported findings. However, few of these are replicated. The most considerable focus has been on genes that might have a role in the proposed mechanism of depression, such as the gene involved in the encoding of serotonin (HTR1A), the serotonin transporter (5HTTP/SLC6A4), or the dopamine receptor (DRD4), and transporter (SLC6A3). Although some have replicated the most significant associations for these genes (most often for the 5HTTP/SLC6A4 gene), the effect size are small, and the sample sizes are smaller than those using GWAS, leading some experts to question the role of statistical error in the positive and negative findings. If some or all of the candidate gene studies are significant, the most likely interpretation of available findings is that much, or most of the genetic heritability for depression is the result of many genes each contributing a small effect, which only becomes meaningful when combined across thousands of genes. It is also possible, however, that there is some rare, still undetected genetic variant.

THE PSYCHOLOGY OF DEPRESSION

A great deal of psychological and sociologic research has also shed light on the pathology of depression. Perhaps the most meaningful contributions come from research on the role of stress and depression.

Stress and Depression

Some clinicians believe that life events play the primary or principal role in depression; others suggest that life events have only a limited role in the onset and timing of depression. The most compelling data indicate that the life event most often associated with the development of depression is losing a parent before age 11 years. The environmental stressor most often associated with the onset of an episode of depression is the loss of a spouse. Another risk factor is unemployment; persons out of work are three times more likely to report symptoms of an episode of major depression than those who are employed.

Personality

No single personality trait or type uniquely predisposes a person to depression; all humans, of whatever personality pattern, can and do become depressed under appropriate circumstances. Persons with certain personality disorders—OCPD, histrionic, and borderline—may be at higher risk for depression than persons with an antisocial or paranoid personality disorder. The latter can use projection and other externalizing defense mechanisms to protect themselves from their inner rage.

ETIOLOGY

As we can see, there is a great deal of data accumulating on various pathologies and dysregulations in the brain and body that are associated with depression. Many experts in the field have attempted to combine various lines of research into a coherent explanation of what causes us to suffer from a depressive disorder. Although there is no single unifying theory, several theories have emerged over the last century that attempt to account for the various clinical, psychological, and biologic findings in depression.

Biologic Theories

The Monoamine Hypothesis. As already noted, the fact that all known antidepressants acted on the monoamines (particularly catecholamines as noted above) coupled with the fact that drugs and diseases that deplete monoamines (e.g., reserpine and Parkinson disease) can cause depressive symptoms led to the supposition that depression is the result of some deficiency or dysregulation in brain monoamines.

Although the theory became, and to a point remains, prevalent, several lines of evidence suggested it was an inadequate explanation for the etiology of depression. Most notably, antidepressants take weeks to work, even though their presumed action of increasing monoamine levels happens quickly, often within hours after administration. Also, there is no convincing evidence of any neurochemical imbalance, for example, in studies of the CSF of depressed patients or postmortem brain tissue.

As noted in our discussion of the pathology of depression, there is good evidence to suggest that neurotransmitters do play an important role, and that receptor or second messenger relationships may explain some of the inconsistent findings. Some have attempted to modify the monoamine hypothesis, suggesting that it remains true, but is more complicated than initially thought. However, a consistent and coherent explanation of the role of neurotransmitters remains elusive, and we still do not know whether their relationship to depression is one of causation or a later effect of the disease.

Brain Dysfunction. Theories of brain dysregulation attempt to incorporate both findings of dysregulation with the increased and decreased responses to various negative stimuli observed in studies. Areas of interest include:

The amygdala. Part of the limbic system, the amygdala appears to be a crucial way station for processing novel stimuli of emotional significance and coordinating or organizing cortical responses.

The hippocampus. Adjacent to the amygdala, the hippocampus is most associated with learning and memory. Emotional or contextual learning appears to involve a direct connection between the hippocampus and the amygdala. Also, the hippocampus regulates the HPA axis by inhibiting activity.

The Prefrontal Cortex (PFC). We think of the PFC as the structure that

holds representations of goals and appropriate responses to obtain these goals. There are areas of specialization. For example, whereas left-sided activation of regions of the PFC is more involved in goal-directed or appetitive behaviors, regions of the right PFC are implicated in avoidance behaviors and inhibition of appetitive pursuits. Subregions in the PFC appear to localize representations of behaviors related to reward and punishment.

The anterior cingulate cortex (ACC). The ACC is involved in attention, motivation, and environmental exploration and appears to help integrate attentional and emotional inputs. The more rostral and ventral region has an affective subdivision that connects extensively with limbic regions of the brain. Activation of the ACC may facilitate control of emotional arousal, particularly when thwarting goal when attainment encountering novel problems.

There are various theories that attempt to integrate various pathologic findings into an understanding of the etiology of depression. Although there are many approaches and variations, many theories broadly fall into one of two categories: neurogenesis hypotheses and neuroplastic hypotheses.

Neurogenesis Hypotheses. Neurogenesis hypotheses suppose that the brain abnormalities leading to depression are the result of abnormalities in development such that there is a deficit in the number of newborn neurons in the brain.

There are several explanations for the cause of this deficit. Some versions attempt to link the role of stress, particularly chronic stress, in causing depression. Stress can cause increased activity in the HPA axis, which results in increased glucocorticoid production. Glucocorticoids are known to decrease neurogenesis. As neurogenesis continues in the adult hippocampus, this may be an area preferentially affected by stress. The hippocampus is then unable to adequately regulate the HPA axis, leading to continued elevated glucocorticoid levels in the brain and further inhibition of neurogenesis.

Neuroplasticity Hypotheses. Neuroplasticity hypotheses propose that the atrophy of already developed neurons causes depression. In this version, rather than a deficit of nerve growth, atrophy occurs in already mature neurons. As noted, chronic stress can increase glucocorticoid levels, which can cause atrophy. It can also decrease the expression of BDNF, which is

essential for the survival, growth, and differentiation of neurons in the brain; the result is atrophy. As this preferentially happens in the hippocampus, this can account for the finding of decreased hippocampal volume in depressed patients.

Psychosocial Theories

Life Events and Environmental Stress. A long-standing clinical observation is that stressful life events more often precede first, rather than subsequent, episodes of mood disorders. One theory proposed to explain this observation is that the stress accompanying the first episode results in long-lasting changes in the brain's biology. As a result, a person has a high risk of undergoing subsequent episodes of a mood disorder, even without an external stressor.

Ms. C, a 23-year-old woman, became acutely depressed when she was accepted to a prestigious graduate school. Ms. C had been working diligently toward this acceptance for the past 4 years. She reported being "briefly happy, for about 20 minutes" when she learned the good news but rapidly slipped into a hopeless state in which she recurrently pondered the pointlessness of her aspirations, cried constantly, and had to physically stop herself from taking a lethal overdose of her roommate's insulin. In treatment, she focused on her older brother, who had regularly insulted her throughout the course of her life, and how "he's not doing well." She found herself very worried about him. She mentioned that she was not used to being the "successful" one of the two of them. In connection with her depression, it emerged that Ms. C's brother had had a severe, life-threatening, and disfiguring pediatric illness that had required much family time and attention throughout their childhood. Ms. C had become "used to" his insulting manner toward her. In fact, it seemed that she required her brother's abuse of her in order not to feel overwhelmed by survivor guilt about being the "healthy, normal" child. "He might insult me, but I look up to him. I adore him. Any attention he pays to me is like a drug," she said. Ms. C's acceptance to graduate school had challenged her defensive and essential compensatory image of herself as

being less successful, or damaged, in comparison with her brother, thereby overwhelming her with guilt. Her depression remitted in psychodynamic psychotherapy as she better understood her identification with and fantasy submission to her brother. (Courtesy of J. C. Markowitz, M.D. and B. L. Milrod, M.D.)

Psychodynamic Theories of Depression. The psychodynamic understanding of depression defined by Sigmund Freud and expanded by Karl Abraham is known as the classic view of depression. That theory involves four key points: (1) disturbances in the infant–mother relationship during the oral phase (the first 10 to 18 months of life) predispose to subsequent vulnerability to depression; (2) depression can be linked to real or imagined object loss; (3) introjection of the departed objects is a defense mechanism invoked to deal with the distress connected with the object's loss; and (4) because the lost object is regarded with a mixture of love and hate, feelings of anger are directed inward at the self.

Ms. E, a 21-year-old college student, presented with major depression and panic disorder since early adolescence. She reported hating herself, crying constantly, and feeling profoundly hopeless in part because of the chronicity of her illness. Even at the time of presentation, she noted her sensitivity to her mother's moods. "My mother's just always depressed, and it makes me so miserable. I just don't know what to do," she said. "I always want something from her, I don't even know what, but I never get it. She always says the wrong thing, talks about how disturbed I am, stuff like that, makes me feel bad about myself." In one session, Ms. E poignantly described her childhood: "I spent a lot of time with my mother, but she was always too tired, she never wanted to do anything or play with me. I remember building a house with blankets over the coffee table and peeking out, spying on her. She was always depressed and negative, like a negative sink in the room, making it empty and sad. I could never get her to do anything." This patient experienced extreme guilt in her psychotherapy when she began to talk about her mother's depression. "I feel so bad," she sobbed. "It's like I'm saying bad things about her. And I love her so much, and I know she loves me. I feel it's so

Cognitive Theory. According to cognitive theory, depression results from specific cognitive distortions present in persons susceptible to depression. These distortions, referred to as depressogenic schemata, are cognitive templates that perceive both internal and external data in ways that are altered by early experiences. Aaron Beck postulated a cognitive triad of depression that consists of (1) views about the self—a negative self-precept, (2) about the environment—a tendency to experience the world as hostile and demanding, and (3) about the future—the expectation of suffering and failure. Therapy consists of modifying these distortions. We summarize the elements of cognitive theory in Table 7-14.

Learned Helplessness. The learned helplessness theory of depression connects depressive phenomena to the experience of uncontrollable events. For example, when dogs in a laboratory are exposed to electrical shocks from which they cannot escape, they showed behaviors that differentiate them from dogs not exposed to such uncontrollable events. The dogs exposed to the shocks would not cross a barrier to stop the flow of electric shock when put in a new learning situation. They remained passive and did not move. According to the learned helplessness theory, the shocked dogs learned that outcomes were independent of responses, so they had both cognitive motivational deficits (i.e., they would not attempt to escape the shock) and emotional deficits (indicating decreased reactivity to the shock). In the reformulated view of learned helplessness as applied to human depression, internal causal explanations may produce a loss of self-esteem after adverse external events. Behaviorists who subscribe to this theory often stress that improvement of depression is contingent on the patient's learning a sense of control and mastery of the environment.

**Table 7-14
Elements of Cognitive Theory**

Element	Definition
Cognitive triad	Beliefs about oneself, the world, and the future
Schemas	Ways of organizing and interpreting experiences
Cognitive distortions	Persistent ways of thinking that are inaccurate and usually negatively biased
Arbitrary inference	Drawing a specific conclusion without sufficient evidence
Specific abstraction	Focus on a single detail while ignoring other, more important aspects of an experience
Overgeneralization	Forming conclusions based on too little and too narrow experience
Magnification and minimization	Over- or undervaluing the significance of a particular event
Personalization	Tendency to self-reference external events without basis
Absolutist, dichotomous thinking	Tendency to place experience into all-or-none categories

Courtesy of Robert M.A. Hirschfeld, M.D. and M. Tracie Shea, Ph.D.

Evolutionary Theory. Some theorists take an evolutionary perspective toward depression. From this perspective, depression is an adaptive response to perceived threats in the environment. From this perspective, depression is an adaptive response to perceived threats in the environment, and the tendency for depressed persons to withdraw from the environment in the face of possible threats could be protective. Beyond threats of bodily harm, social threats (e.g.,of exclusion or defeat) could also be considered threats in that such social threats can reduce one's perceived fitness, and hence, the desirability of a mate. The depressive response in which one decreases activity, withdraws from social situations, and approaches novel situations with a negative bias ("that person will think I am a loser") could be

interpreted as adaptive ways to reduce risk and avoid further social failures. There are many varieties of evolutionary theory, some of which stress the adaptive benefit of depression, others which see it as an outmoded response which may have had a benefit in ancient societies, but is counterproductive in our modern world. Other versions see the basic ability to vary mood as adaptive but suggest depression is a dysregulation of that normal function. These theories are difficult to test, as it is challenging to test the fitness of a particular trait that is very common in a population.

Integrative Approaches

It remains difficult, if not impossible, to incorporate all the various observations and research findings on depression into one grand unified theory. However, the various attempts by investigators and theoreticians to incorporate these findings have certain common features.

It seems clear that there exists some genetic vulnerability that puts persons at risk for depression. Such persons who then encounter stress, either external or internal, have epigenetic changes that differ from normal responses to stress; for example, they may be less able to transcribe certain growth factors in response to stress. This deficit results in subtle neuronal loss, and this loss is particularly apparent in some vulnerable areas (e.g., the hippocampus). The result is a disruption of the usual regulatory systems in the brain, causing changes in the expressions of transmitters, hormones, and other regulatory systems. This causes the physical changes that we associate with depression, and our behavioral response to this is the subjective feeling of depression.

Anxiety Disorders

Everyone experiences anxiety. The experience of anxiety has two components: the awareness of the physiologic sensations (e.g., palpitations and sweating) and the awareness of being nervous or frightened. It is a diffuse, unpleasant, vague sense of apprehension, usually accompanied by autonomic symptoms. Although the physical and emotional symptoms of anxiety are similar to "fear," it differs from fear in that it is not a response to an overt danger, but rather an impending one. Both fear and anxiety are normal adaptive responses to a potentially dangerous environment. They make us better prepared to survive a danger, either through fight, flight, or freezing, as the situation may warrant.

Much of psychology research and psychoanalytic thought is devoted to understanding what we would consider being normal anxiety. This chapter will concentrate, however, on pathologic anxiety: when it is inappropriately triggered and maladaptive, hence an anxiety disorder.

Anxiety disorders are the most prevalent psychiatric syndromes in the U.S. population. Nearly one-fifth of adults report a lifetime history of one of the major anxiety disorders, and 1 in 10 suffer from a current anxiety disorder. Anxiety disorders are associated with social impairment and, when occurring in childhood, can interfere with healthy development, having consequences for later social and occupational functioning. Worldwide, they are the sixth most significant contributor to nonfatal health loss globally, and they explain 10 percent of the disability-adjusted life years for all mental, neurologic, and substance use disorders, second only to major depression.

THE CLINICAL PRESENTATION

The anxious patient has a variety of symptoms, particularly cognitive and physical. Some of the symptoms, particularly the autonomic ones, are observable and quantifiable, making it easier to develop objective measures. It also makes research on these disorders somewhat more straightforward.

Anxiety can have a variety of physical manifestations. The most common is its effect on the autonomic system, including such symptoms as headache, perspiration, palpitations, tightness in the chest, and mild stomach discomfort. It can also produce motor symptoms, such as restlessness, indicated by an inability to sit or stand still for long. The particular constellation of symptoms present during anxiety tends to vary among persons.

The anxious individual may describe themselves as "nervous" or "frightened." Their mood is frequently observable, particularly in patients who are experiencing a panic attack, as a classically fearful expression: eyes and mouth open, eyebrows raised. In patients with more chronic forms of anxiety, the expression may be more blunted and more akin to a depressed affect.

Thoughts may be more rapid, and in cases of severe anxiety, may become more disorganized. In extreme forms, a person may have great difficulty thinking clearly. For example, during a panic attack, a patient may ruminate or stammer.

In the setting of acute anxiety, the thoughts are focused on the perceived cause of the anxiety. Patients may catastrophize and overestimate the danger they are facing. In the case of a panic attack, somatic concerns of death from a cardiac or respiratory problem may be the primary focus of patients' attention during panic attacks. Patients may believe that the palpitations and chest pain indicate that they are about to die. As many as 20 percent of such patients have syncopal episodes during a panic attack. The patients may present in emergency departments as young, physically healthy persons who nevertheless insist that they are about to die from a heart attack. As anxiety becomes chronic, thoughts may take the form of more negative thinking.

Although hallucinations are rare, patients with severe anxiety may have distortions in perception, not only of time and space but also of persons and the meanings of events.

In the proper dose, anxiety can help attention by increasing our alertness and focusing our attention. However, in excess, it can impair cognition.

Patients with severe anxiety can become confused. They can have difficulty focusing their attention, and as a result, may have trouble with recall.

Usually, anxiety does not reach a level where it significantly affects insight or judgment. However, patients can become selective in their interpretation of the environment, focusing on specific aspects and neglecting others to prove that they are justified in their reactions.

Although the patients do not tend to talk about suicidal ideation, they are at increased risk of committing suicide. Some studies have found that the lifetime risk of suicide in persons with panic disorder is higher than it is in persons with no mental disorder.

Presentation in Special Populations

Anxiety has many possible disorders, and different populations can present differently. For example, children or the elderly may present more with somatic symptoms than adults.

Certain cultural groups may have syndromes unique to their group, some of which represent culturally specific understandings of their body. Examples include the multiple anxiety syndromes related to the fear of "wind attacks" in Cambodians, or the syndrome *of Ataque de Nervios* (attack of nerves) in Puerto Rican and Dominican patients. In most cases, anxiety symptoms do not differ from those in other cultures. However, the emphasis may be on the specific ones relevant to beliefs about the underlying cause. In most cases, a full history and examination can elucidate the problem. It is often helpful to seek a cultural consultation for an understanding of the particular syndrome. In the past, there have been some broad overgeneralizations about different ethnic or cultural groups. However, these often reflect a bias and are usually not helpful.

DIAGNOSIS

Within this category, there are several disorders, including panic disorder (with and without agoraphobia), agoraphobia (without a history of panic disorder), specific phobia, social phobia, and generalized anxiety disorder.

Panic Disorder

Panic disorder is an acute intense attack of anxiety (a panic attack) accompanied by feelings of impending doom. The anxiety occurs during discrete periods of intense fear that can vary from several attacks during 1 day to only a few attacks during a year. Patients with panic disorder present with several comorbid conditions, most commonly agoraphobia, which refers to a fear of or anxiety regarding places from which escape might be difficult.

A panic attack is a sudden period of intense fear or apprehension that may last from minutes to hours. It is a symptom, and many disorders and situations besides panic disorder can cause panic attacks.

Mrs. K was a 35-year-old woman who initially presented for treatment at the medical emergency department at a large university-based medical center. She reported that while sitting at her desk at her job, she had suddenly experienced difficulty breathing, dizziness, tachycardia, shakiness, and a feeling of terror that she was going to die of a heart attack. A colleague drove her to the emergency department, where she received a full medical evaluation, including electrocardiography and routine blood work, which revealed no sign of cardiovascular, pulmonary, or other illness. She was subsequently referred for psychiatric evaluation, where she revealed that she had experienced two additional episodes over the past month, once when driving home from work and once when eating breakfast. However, she had not presented for medical treatment because the symptoms had resolved relatively quickly each time, and she worried that if she went to the hospital without ongoing symptoms, "people would think I'm crazy." Mrs. K reluctantly took the phone number of a local psychiatrist but did not call until she experienced the fourth episode of a similar nature. (Courtesy of Erin B. McClure-Tone, Ph.D. and Daniel S. Pine, M.D.)

Table 8-1 compares the different approaches to diagnosing panic disorder.

Table 8-1
Panic Disorder

DSM-5	ICD-10

Diagnostic name	Panic Disorder	Panic disorder (episodic paroxysmal anxiety)
Duration	1 mo of worry after 1 panic attack Panic attacks occur during a discrete period	

Symptoms	Panic attacks:
	Cardiopulmonary:
	  • Feeling short of breath
	  • Palpitations
	  • Chest discomfort
	Gastrointestinal:
	  • Nausea or GI discomfort
	Skin and systemic:
	  • Sweating
	  • Chills or feeling flushed
	Neurologic:
	  • Tremulousness
	  • Dizziness
	  • Numbness or tingling
	Psychiatric:
	  • Derealization or depersonalization
	  • Fear of losing control
	  • Fear of dying
	Symptoms are abrupt and unpredictable
	Persistent symptoms between attacks, including:
	Anticipatory anxiety: fearing further attacks
		Recurrent attacks of severe anxiety or panic
		Unpredictable
		Physiologic symptoms:
		  • Chest pain
		  • Palpitations
		  • Difficulty breathing
		  • Sweating
		  • Dizziness
		Additional symptoms
		  • Depersonalization
		  • Derealization
		  • Fear of losing control
		  • Fear of dying

	Avoidance behaviors: trying to avoid real or imagined triggers to prevent another attack	
Required number of symptoms	*Panic attack:* 4+ symptoms ≥1 attack Avoidance behavior or anticipatory anxiety: 1+ month	
Exclusions (not result of):	Substance use Another medical condition Another mental disorder	Another mental illness
Comments	DSM-5 also includes a "Panic Attack Specifier" for discrete panic attacks without the additional criteria for a full panic disorder	

The diagnosis includes a variety of symptoms, including somatic, cognitive, and mood. Patients can feel the physical symptoms in many organs and systems, including cardiorespiratory, gastrointestinal, and otoneurologic. Panic attacks can occur as a part of another mental disorder, particularly the phobias and PTSD. They may or may not be associated with an identifiable situational stimulus and unexpected panic attacks are not uncommon. Some panic attacks do not fit easily into the distinction between unexpected and expected. We call these *situationally predisposed panic attacks*. They may or may not occur when encountering a specific trigger, or they may occur either immediately after exposure or after a considerable delay.

In the DSM-5, to be diagnosed with a panic disorder, a patient must have recurrent, unexpected attacks. This requirement is to help distinguish the disorder from the phobias and other possible causes of panic attacks.

Agoraphobia

Agoraphobia refers to a fear of or anxiety regarding places from which escape might be difficult. It can be the most disabling of the phobias because it can significantly interfere with a person's ability to function in work and social situations outside the home. Although agoraphobia often coexists with panic disorder, in that patients are afraid to leave the safety of home lest they have a panic attack in a public place, DSM-5 considers agoraphobia a separate condition that may or may not be comorbid with panic disorder. Often patients with agoraphobia alone still have some measure of anxiety, "panic-like" symptoms, although those symptoms may not reach the level of an actual panic attack.

Mrs. W was a 33-year-old married woman. She visited an anxiety clinic, reporting that she felt like she was having a heart attack whenever she left her home. Her disorder began 8 years earlier while attending a yoga class when she suddenly noticed a dramatic increase in her heartbeat, felt stabbing pains in her chest, and had difficulty breathing. She began sweating and trembling and felt dizzy. She immediately went to the emergency department, where they performed an electrocardiogram. No abnormalities were detected. Over the next few months, Mrs. W experienced similar attacks of 15 to 30 minutes' duration about four times per month. She often sought medical advice after each episode, and each time no physical abnormalities were detected. After experiencing a few of these attacks, Mrs. W became afraid of having an attack away from home and would not leave her home unless necessary, in which case she needed to have her cell phone or be accompanied by someone. Even so, she avoided crowded places such as malls, movie theaters, and banks, where rapid escape is sometimes blocked. Her symptoms and avoidance dominated her life, although she was aware that they were irrational and excessive. She experienced mild depression and restlessness and had difficulty sleeping.

Patients with agoraphobia rigidly avoid situations in which it would be challenging to obtain help. They prefer to be accompanied by a friend or a family member when leaving home, especially if their destination is crowded or closed-in. Severely affected patients may simply refuse to leave the house.

Patients may be terrified that they are going "crazy."

Table 8-2 compares the different approaches to diagnosing agoraphobia. Several situations might cause anxiety, some involving confining spaces (public transportation, elevators, stores), open spaces (parks, shopping centers), or crowds. What they have in common is the fact that a person is away from home and safety and cannot quickly return to it.

Specific Phobia

The term *phobia* refers to excessive fear of a specific object, circumstance, or situation. A *specific phobia* is an intense, persisting fear of an object or situation, considered dangerous. The fear should be out of proportion to the actual threat. The diagnosis of specific phobia requires the development of intense anxiety, even to the point of panic, when exposed to the feared object. Persons with specific phobias may anticipate harm, such as being bitten by a dog, or may panic at the thought of losing control; for instance, if they fear elevators, they may also worry about fainting after the door closes.

**Table 8-2
Agoraphobia**

	DSM-5	ICD-10
Diagnostic name	Agoraphobia	Agoraphobia
Duration	≥6 mo	

Symptoms	Fear or anxiety from:
	    Public transportation
	    Open spaces
	    Confined spaces
	    Being in a line or in a crowd
	    Being alone outside of home
	Avoidance of the situations, due to:
	    Fear of having a panic attack while there
	    Or, no access to a companion
		Fear of:
		    Leaving home
		    Going to a public place
		    Going to a crowded place
		    Traveling alone

	to help withstand the situation Fear and avoidance is out of proportion to the potential threat	Avoidance of anxiety-provoking situations Frequently associated with panic disorders
Required number of symptoms	At least 1 of the above sources of fear	
Psychosocial consequences of symptoms	Marked distress or impairment	
Exclusions (not result of):	Another medical condition Another mental disorder	
Comments	This is for cases in which the above occurs without a panic disorder, despite the fear of having one	

Table 8-3
Specific Phobia

	DSM-5	ICD-10
Diagnostic name	Specific Phobia	Specific (Isolated) Phobias
Duration	Persistent and lasting ≥6 months	
Symptoms	Fear/anxiety about an object or situation Exposure to the object/situation	Phobias, restricted to highly specific situations, objects, or activities Exposure to the above causes panic

	causes immediate fear/anxiety	
	Avoidance behaviors: of the object or situation	
	The fear/anxiety is out of proportion to the likely threat	
Required number of symptoms	All the above	
Psychosocial consequences of symptoms	Marked distress or impairment	
Exclusions (not result of):	Another mental disorder	

Symptom specifiers	Animals
	Natural environment
	Blood–injection–injury
	  Fear of blood
	  Fear of injections and transfusions
	  Fear of other medical care
	  Fear of injury
	Situational
	Other	

Comments		Also contains categories for "Other phobic anxiety disorder" and an unspecified type

Mr. S was a successful lawyer who presented for treatment after his firm, to which he had previously been able to walk from home, moved to a new location that he could only reach by driving. Mr. S reported that he was "terrified" of driving, particularly on highways. Even the thought of getting into a car led him to worry that he would die in a fiery crash. His thoughts were associated with intense fear and numerous somatic symptoms, including a racing heart, nausea, and sweating. Although the thought of driving was terrifying in and of itself, Mr. S became nearly incapacitated when he drove on busy roads, often having to pull over to vomit. (Courtesy of Erin B. McClure-Tone, Ph.D. and Daniel S. Pine, M.D.)

Table 8-3 compares the different approaches to diagnosing specific phobia. There are many possible objects of the fear, including things (animals), environments (storms, dark rooms), situations (driving, flying, blood injections), and many other things that do not fit into these categories. What they have in common is the irrational fear that the object of one's fear is harmful or dangerous.

In each case, the anxiety usually occurs immediately after exposure to the object or situation. The result is either avoidance or painful endurance. It should last for at least 6 months.

Social Anxiety Disorder

Social anxiety disorder (also referred to as *social phobia*) involves the fear of social situations, including situations that involve scrutiny or contact with strangers. The term social anxiety reflects the distinct differentiation of social anxiety disorder from a specific phobia, which is the intense and persistent fear of an object or situation. Persons with social anxiety disorder are fearful of embarrassing themselves in social situations (i.e., social gatherings, oral presentations, meeting new people). They may have specific fears about performing specific activities such as eating or speaking in front of others, or they may experience a vague, nonspecific fear of "embarrassing oneself." In either case, the fear in social anxiety disorder is of the embarrassment that

may occur in the situation, not the situation itself.

Ms. B was a 29-year-old computer programmer who presented for treatment after she was offered a promotion to a managerial position at her firm. Although she wanted the raise and the increased responsibility that would come with the new job, which she had agreed to try on a probationary basis, Ms. B reported that she was reluctant to accept the position because it required frequent interactions with employees from other divisions of the company, as well as occasional public speaking. She stated that she had always felt nervous around new people, whom she worried would ridicule her for "saying stupid things" or committing a social faux pas. She also reported feeling "terrified" to speak before groups. These fears had not previously interfered with her social life and job performance. However, since starting her probationary job, Ms. B reported that they had become problematic. She noted that when she had to interact with others, her heart started racing, her mouth became dry, and she felt sweaty. At meetings, she had sudden thoughts that she would say something very foolish or commit a terrible social gaffe that would cause people to laugh. As a consequence, she had skipped several important meetings and left others early. (Courtesy of Erin B. McClure-Tone, Ph.D. and Daniel S. Pine, M.D.)

Table 8-4 compares the different approaches to diagnosing social anxiety disorder. Many people feel anxiety in social situations, and it is rare to find the person who feels no anxiety over speaking in public or attending a party where they will not know anyone. The key feature in social anxiety disorder is that this anxiety is significant to the point of being disabling, meaning that it is sufficient to cause clinically significant distress or impairment. It also occurs while one is scrutinized, and includes a fear of negative judgment. Furthermore, DSM-5 emphasizes that the fear should occur in situations in which the individual is under scrutiny and that the fear is of being "negatively evaluated" (embarrassed or rejected).

Table 8-4

Social Anxiety Disorder

	DSM-5	ICD-10
Diagnostic name	Social anxiety disorder	Social anxiety disorder
Duration	≤6 mo	
Symptoms	Fear of being judged/scrutinized in social situation Fear that others will notice the anxiety, causing additional judgment, embarrassment, or rejection Avoidance behaviors: of the feared social situations The fear/anxiety is out of proportion to the social risk	Fear of being judged/scrutinized by others Avoidance behaviors: of the feared social situations May be associated with low self-esteem May cause panic attacks
Required number of symptoms	All the above	
Psychosocial consequences of symptoms	Marked distress and/or impairment	
Exclusions (not result of):	Another mental illness Another medical illness	
Symptom specifiers	Performance only (performance anxiety)	

DSM-5 includes a specifier for performance anxiety ("performance only"), in which the fear is limited to public speaking or performance.

Generalized Anxiety Disorder

Generalized anxiety disorder is defined as excessive anxiety and worries about several events or activities most of the time for at least 6 months. The worry is difficult to control and is associated with somatic symptoms, such as muscle tension, irritability, difficulty sleeping, and restlessness. The worry usually involves a broad swath of everyday life, such as simple daily activities, timeliness, finances, or health. These are ordinary worries for many people. However, patients with a generalized anxiety disorder worry about them to the point where catastrophe seems possible, likely, and imminent. Another feature is that these concerns cannot be prioritized or put aside to deal with more pressing matters that may pop up. This inability to prioritize is a key feature that contributes to the pathologic effect that this disorder has on functioning.

Mr. G was a successful, married, 28-year-old teacher who presented for a psychiatric evaluation to treat mounting symptoms of worry and anxiety. Mr. G noted that for the preceding year, he had become more and more worried about his job performance. For example, although he had always been a respected and popular lecturer, he found himself worrying about his ability to engage students and convey the material effectively. Similarly, although he had always been financially secure, he increasingly worried that he was going to lose his wealth due to unexpected expenses. Mr. G noted frequent somatic symptoms that accompanied his worries. For example, he often felt tense and irritable while he worked and spent time with his family, and he had difficulty distracting himself from worries about the upcoming challenges for the next day. He reported feeling increasingly restless, especially at night, when his worries kept him from falling asleep. (Courtesy of Erin B. McClure-Tone, Ph.D. and Daniel S. Pine, M.D.)

Table 8-5 compares the different approaches to diagnosing generalized anxiety disorder. The distinction between generalized anxiety disorder and normal anxiety is that the worry is excessive, difficult to control, and causes impairment.

Objective Rating Scales for the Disorder

There are many scales for measuring anxiety. Some popular examples are the Beck Anxiety Inventory (BAI), Hospital Anxiety and Depression Scale (HADS), and the Generalized Anxiety Disorder scale (GAD-7), but there are many more. Many other broader scales include measures of anxiety. Some scales measure anxiety per se, while others help to identify a specific disorder. Scales may also differentiate between state and trait anxiety, which is situational anxiety versus anxiety that seems characteristic for a person and independent of the situation. An example for the latter is the State-Trait Anxiety Inventory.

DIFFERENTIAL DIAGNOSIS

Distinguishing Between the Anxiety Disorders

Anxiety disorders have overlapping symptoms. Sometimes it is difficult to distinguish between panic disorder, on the one hand, and specific and social phobias, on the other hand. Some patients who experience a single panic attack in a specific setting (e.g., an elevator) may go on to have long-lasting avoidance of the specific setting, regardless of whether they ever have another panic attack. These patients meet the diagnostic criteria for a specific phobia, and clinicians must use their judgment about what is the most appropriate diagnosis. In another example, a person who experiences one or more panic attacks may then fear to speak in public. Although the clinical picture is almost identical to the clinical picture in social anxiety disorder, we would not diagnose a social anxiety disorder because the avoidance of the public situation is based on fear of having a panic attack rather than on fear of the public speaking itself.

Table 8-5
Generalized Anxiety Disorder

	DSM-5	ICD-10
Diagnostic name	Generalized Anxiety Disorder	Generalized Anxiety Disorder

Duration	≤6 mo	
Symptoms	Excessive anxiety/worry Difficulty controlling/ managing worry *Anxiety characterized by:* • Restlessness • Fatigue • Poor concentration • Irritability • Muscle tension • Insomnia	Persistent anxiety *Anxiety characterized by:* • Shaking • Muscle tension • Sweating • Lightheadedness • Palpitations • GI symptoms
Required number of symptoms	First two criteria and 3+ of the specific symptoms	
Psychosocial consequences of symptoms	Marked distress and/or impairment	
Exclusions (not result of):	• Another mental disorder • Substance use • Another medical condition	Anxiety not associated with an object, event, or situation

Other Psychiatric Disorders

The differential diagnosis for agoraphobia includes all the psychiatric disorders that can cause anxiety or depression. A panic disorder is the most common cause of agoraphobia, and a separate diagnosis of agoraphobia is not necessary. Other disorders include major depressive disorder, schizophrenia, paranoid personality disorder, avoidant personality disorder, and dependent personality disorder.

Medical Disorders

Many medical disorders can cause anxiety or have symptoms that overlap with anxiety disorders.

Several medical conditions produce symptoms that are similar to panic disorder. Panic attacks are associated with a variety of endocrinologic disorders, including both hypo- and hyperthyroid states, hyperparathyroidism, and pheochromocytomas. Episodic hypoglycemia associated with insulinomas can also produce panic-like states, as can primary neuropathologic processes. These include seizure disorders, vestibular dysfunction, neoplasms, or the effects of both prescribed and illicit substances on the CNS. Finally, disorders of the cardiac and pulmonary systems, including arrhythmias, chronic obstructive pulmonary disease, and asthma, can produce autonomic symptoms and accompanying crescendo anxiety that can be difficult to distinguish from panic disorder. Clues of an underlying medical etiology to panic-like symptoms include the presence of atypical features during panic attacks, such as ataxia, alterations in consciousness, or bladder dyscontrol, onset of panic disorder relatively late in life, and physical signs or symptoms indicative of a medical disorder.

COMORBIDITY

Depressive symptoms are often present in panic disorder, and in some patients, a depressive disorder coexists with the panic disorder, and depression can complicate the symptom picture in anywhere from 40 to 80 percent of all patients, as estimated by various studies.

In addition to agoraphobia, other phobias and OCD can coexist with panic disorder.

Alcohol and other substance use disorders occur in about 20 to 40 percent of all patients, and OCD may also develop.

COURSE

Panic attacks, by definition, have a sudden onset and relatively short duration. The first panic attack is often completely spontaneous, although panic attacks occasionally follow excitement, physical exertion, sexual activity, or moderate emotional trauma.

The attack often begins with 10 minutes of rapidly increasing symptoms. The significant mental symptoms are extreme fear and a sense of impending death and doom. Patients usually cannot name the source of their fear; they may feel confused and have trouble concentrating. The physical signs often include tachycardia, palpitations, dyspnea, and sweating. Patients often try to leave whatever situation they are in to seek help. The attack generally lasts 20 to 30 minutes and rarely more than an hour.

Panic disorder usually has its onset in late adolescence or early adulthood, although onset during childhood, early adolescence, and midlife do occur. Some data implicate increased psychosocial stressors with the onset of panic disorder, although in most cases, there are no identifiable psychosocial stressors.

Panic disorder is a chronic disorder, although its course is variable, both among patients and within a single patient. The available long-term follow-up studies of panic disorder are difficult to interpret because they have not controlled for the effects of treatment. Nevertheless, about 30 to 40 percent of patients seem to be symptom-free at long-term follow-up, about 50 percent have symptoms that are sufficiently mild not to affect their lives significantly, and about 10 to 20 percent continue to have significant symptoms.

After the first one or two panic attacks, patients may be relatively unconcerned about their condition; with repeated attacks, however, the symptoms may become a significant concern. Between attacks, patients may have anticipatory anxiety about having another attack. Patients may attempt to keep the panic attacks secret and thereby cause their families and friends concern about unexplained changes in behavior. The frequency and severity of the attacks can fluctuate. Panic attacks can occur several times in a day or less than once a month. Excessive intake of caffeine or nicotine can exacerbate the symptoms.

When agoraphobia is part of a panic disorder, improving panic symptoms often also improves agoraphobia. For rapid and complete reduction of agoraphobia, behavior therapy is useful. Agoraphobia without a history of panic disorder is often incapacitating and chronic, and depressive disorders and alcohol use disorder often complicate its course.

The presence of comorbid disorders, particularly alcohol and substance use disorders, complicates the course of anxiety disorders. Patients with good premorbid functioning and symptoms of brief duration tend to have a

favorable prognosis.

Most of the other anxiety disorders also have long-term courses with multiple relapses. Overall these are all chronic disorders. Generalized anxiety disorder commonly has multiple relapses, although some may occur long after the initial episode, sometimes giving a false sense of security. Clinicians should regularly monitor the symptoms.

Most of these disorders also have an increased risk of suicide, and clinicians should monitor this as well.

TREATMENT APPROACH

With treatment, most patients exhibit dramatic improvement in their anxiety symptoms. Treatments include pharmacologic, psychologic, and combined treatments for all anxiety disorders. Meta-analyses generally suggest that pharmacologic treatment has the largest effect size of the various options. However, depending on the anxiety disorder, there are many pharmacologic, psychotherapeutic, and combined options available.

Hospitalization

Patients rarely require hospitalization unless they need a diagnostic workup, for example, to rule out a medical cause. Also, we may hospitalize patients with comorbid disorders such as substance use or those who are suicidal.

Pharmacotherapy

Among the medication options, selective serotonin reuptake inhibitors are the first-line agents for most anxiety disorders, including panic disorder, generalized anxiety disorder, and social anxiety disorder. Some non-SSRIs are also useful, for example, venlafaxine for panic disorder, generalized anxiety disorder, and social anxiety disorder. Tricyclic antidepressants are useful for panic disorder as well, although less popular due to their side effects. Many clinicians consider mirtazapine to be useful for anxiety disorders, owing to its sedative effect. However, there are few studies of its use for anxiety disorder.

Benzodiazepines remain one of the most popular medications used for anxiety disorder, perhaps the most popular. Most treatment guidelines

suggest that they be mostly limited to short-term use, either as an adjunct to SSRIs during the initial treatment phase or for acute use during exacerbations of the anxiety. Generally, most guidelines recommend that we should only consider long-term benzodiazepines for patients who do not respond or cannot tolerate the SSRIs. The main concerns are the potential for dependence, as well as the cognitive and other side effects. Tolerance to the anxiolytic effects does not seem to develop.

Antipsychotics and anticonvulsants are not recommended as initial therapy but may have some role for treatment-resistant patients. Among them, quetiapine is popular and may be useful as a second-line treatment for generalized anxiety disorder.

Buspirone is an azapirone, and effective for the treatment of generalized anxiety disorders. It is given in three divided doses during the day. The time to effect is similar to that for antidepressants, several weeks, and may take as long as several months. It may be useful as an adjunct to antidepressants for other anxiety disorders; however, most of the evidence is anecdotal.

β-Blockers, such as propranolol, are sometimes used for anxiety disorders, particularly social anxiety disorder. However, the available evidence does not support this use. Anecdotally, many consider it useful for social anxiety, particularly performance anxiety. The presumed mechanism is the drug's ability to block many of the physiologic symptoms of anxiety. However, there is little data to support this, and at least one study showed no effect. One study concluded it might be useful for performance anxiety—specifically musical performances—however, it also had significant side effects that could impair performance.

Antihistamines, such as hydroxyzine, are also used, particularly as alternatives to benzodiazepines for acute treatment. It has some evidence for its use in generalized anxiety disorder. We know little about its long-term effect.

Table 8-6 lists the common classes of drugs used for anxiety disorders and the evidence supporting their use.

Treatment Approach. Table 8-7 gives some pointers for using medications to treat patients with anxiety.

For most anxiety disorders, a conservative approach is, to begin with, an SSRI. Benzodiazepines are most useful when a patient requires rapid control

of severe anxiety symptoms. In those cases, a short-term benzodiazepine, such as lorazepam or alprazolam, is helpful in the short term. Concurrently, an SSRI should be started and slowly increased.

For panic disorder, SSRIs or the serotonin–norepinephrine reuptake inhibitor (SNRI) venlafaxine are first-line options. Tricyclic antidepressants or MAOIs are effective but less preferably given their side effects. Other agents, such as mirtazapine, are other second-line options. As mentioned, the benzodiazepines are effective options but mainly used for short-term use or exacerbations. Long-term antidepressant therapy is useful for preventing relapse, with studies suggesting that the beneficial effects last for up to 1 to 3 years. When appropriate, maintenance therapy should be discontinued very slowly.

For generalized anxiety disorder, the approach is similar, with SSRIs and SNRIs being the first-line treatments. Reasonable alternatives if those are not effective include agomelatine, pregabalin, buspirone, and quetiapine.

For social anxiety disorder, the approach is similar to those already described, with SSRIs and SNRIs being the first-line choice. Pregabalin and clonazepam also have strong evidence, although the same caveats for other benzodiazepines apply to clonazepam. Phenelzine is effective as well but is rarely used because of the side effects. Tricyclic antidepressants, buspirone, and quetiapine are not recommended owing to their side effects. As noted above, β-blockers may be useful for performance anxiety. However, their use does not appear to generalize to other types of social anxiety.

Table 8-6
Evidence-Based Recommendations for Monotherapy of Anxiety Disorders

Classes and Agents	Anxiety Disorders		
	GAD	PD	SAD
SSRIs	First line	First line	First line
SNRIs	First line	First line	First line
TCAs	Second line	Second line	Not

			recommended
MAOIs	Insufficient evidence	Second line	Second line
RIMA-Moclobemide	Insufficient evidence	Insufficient evidence	Second Line
Other Psychotropics—Agomelatine, Buspirone, Mirtazapine	Second line	Second line	Second line
Benzodiazepines	Second line	Second line	Second line
Atypical Antipsychotics—Quetiapine	Second line	Insufficient evidence	Not recommended
Anticonvulsant—Pregabalin	Second line	Insufficient evidence	Second line

Note: Beta-adrenergic blocking agents are recommended only for performance anxiety.

RIMA, reversible monoamine oxidase inhibitor; GAD, generalized anxiety disorder; PD, panic disorder; SAD, social anxiety disorder.

In the case of specific phobia, psychotherapies, particularly behavioral therapies, are the first-line choice. SSRIs may be helpful, although there are few studies of SSRIs for this disorder.

For agoraphobia, the main goal of pharmacotherapy is to treat the panic attacks that are usually comorbid. Early studies did not support the use of medications for "pure" agoraphobia; however, there has been little research since.

Psychosocial Therapies

There is strong support for a variety of psychosocial therapies for anxiety disorders, including cognitive-behavioral therapy (CBT), behavioral therapies, and interpersonal therapy. Studies of CBT suggest it has a substantial effect on generalized anxiety disorder, panic disorder, and social anxiety disorder, although this evidence is tempered by concerns about

treatment bias in the studies. Some treatment guidelines consider individual CBT to be a first-line treatment for social anxiety disorder. Group psychotherapy, mainly using CBT techniques, is also useful for social anxiety disorder. In vivo exposure therapy is the treatment of choice for specific phobia.

Cognitive Therapy. The two major foci of cognitive therapy for panic disorder are instruction about a patient's false beliefs and information about panic attacks. The instruction about false beliefs centers on the patient's tendency to misinterpret mild bodily sensations as indicating impending panic attacks, doom, or death. The information about panic attacks includes explanations that when panic attacks occur, they are time-limited and not life-threatening.

Table 8-7
Pharmacotherapy of Anxiety Disorders: Key Pointers

- SSRIs are the first-line option.
- Start low and go slow.
- Routine increase to higher doses not recommended, but a subgroup might benefit.
- Concomitant benzodiazepines as initial therapy in the short term may be useful.
- 8–12 weeks of pharmacotherapy at optimum doses may be needed to assess efficacy.
- Good evidence for the benefit of maintenance treatment at least up to 6 months.

Behavioral Therapies. In behavior therapy, the underlying assumption is that change can occur without the development of psychologic insight into underlying causes. Techniques include positive and negative reinforcement, systematic desensitization, flooding, implosion, graded exposure, response prevention, thought stopping, relaxation techniques, panic control therapy, self-monitoring, and hypnosis. For patients with specific phobias, the approach usually involves gradually increasing the patient's exposure to the

feared stimulus (e.g., climbing to increasingly higher floors in a building for a patient with a fear of heights) while practicing relaxation techniques until the patient masters each successive step.

Interpersonal Psychotherapy. There is good evidence for interpersonal psychotherapy, particularly interpersonal skills training for social anxiety disorder. The assumption is that such patients have interpersonal deficits that contribute to their anxiety and lack the skills to interact with others effectively. The result is that patients experience more of the "punishments" and less of the rewards from social interaction than most other people.

Virtual Therapy. Computer programs exist that allow us to treat a variety of anxiety disorders, including agoraphobia, specific phobia, and social anxiety disorder. As an example, patients with agoraphobia may experience a virtual environment in which they are in a crowded space (e.g., a supermarket). As they identify with the avatars in repeated computer sessions, they can learn to master their anxiety until they are ready to try the exposure in real life. This approach is particularly useful for situations that are not easily reproduced inside or near a clinician's office (i.e., flying).

Supportive Psychotherapy. Supportive psychotherapy involves the use of psychodynamic concepts and a therapeutic alliance to promote adaptive coping. Adaptive defenses are encouraged and strengthened, and maladaptive ones are discouraged. The therapist assists in reality testing and may offer behavioral advice. Although lacking empirical support, clinicians frequently incorporate some degree of supportive psychotherapy as an adjunct to medication.

Insight-Oriented Psychotherapy. In insight-oriented psychotherapy, the goal is to increase the patient's development of insight into psychologic conflicts that, if unresolved, can manifest as symptomatic behavior. For a time, it was the classic treatment for many types of anxiety, with the assumption that the anxiety represented an underlying psychodynamic conflict. Some studies suggest that psychodynamic psychotherapy can help decrease anxiety symptoms, and may have a lasting effect. However, the studies tend to have methodologic problems, and we lack the large,

comparative studies needed to determine efficacy.

THE EPIDEMIOLOGY OF THE DISORDER(S)

Incidence and Prevalence

Anxiety disorders make up one of the most common groups of psychiatric disorders. The National Comorbidity Study reported that one of four persons met the diagnostic criteria for at least one anxiety disorder and that there is a 12-month prevalence rate of 17.7 percent.

Most epidemiologic studies of panic disorder suggest a 12-month prevalence between 0.2 and 1.1 percent. The lowest rate reported rate was 0.1 percent (Nigeria), and the highest was 6.9 percent (Italy), with a median of 2.3 percent.

Most epidemiologic studies of generalized anxiety disorder suggest a 12-month prevalence between about 2.1 and 3.1 percent in the United States. The ranges vary widely, with ranges from 0 percent (Nigeria) to 2.6 percent (Germany).

The 12-month prevalence of social anxiety disorder varies widely across regions. The United States has the highest reported rates (6.8 percent), and China the lowest (0.2 percent). The median is about 4 percent to 5 percent. It may be that these differences involve differing cultural concepts of social fears or even difficulties in translating this concept to different cultures.

The 12-month prevalence of agoraphobia is mostly consistent across regions, with a range from 0 (China) to 0.8 percent (U.S.). An exception is South Africa, with a reported rate of 4.8 percent.

The rates of specific phobias vary widely, with a range of 1.9 percent (China) to 8.7 percent (U.S.).

Table 8-8 compares the 12-month and lifetime prevalence of anxiety disorders across different countries.

Sex

Women have higher rates of almost all anxiety disorders than do men. The difference is twofold for most disorders. The exception is social anxiety disorder, where the ratio is about equal. This difference is true across all ages but is most evident during early and mid-adulthood.

Age

The anxiety disorders have one of the earliest onsets of all psychiatric disorders. Most of the disorders begin in childhood or adolescence; the median age is 12.

In general, phobic disorders are the most stable of the disorders over time. Panic and generalized anxiety disorder are much like major depressive disorder in that they tend to have exacerbations and remissions over the life span.

Sociocultural and Ethnic Variables

Anxiety disorders appear to be common in persons of lower socioeconomic status and educational level. However, these relationships are very complex.

Some studies have reported higher rates of anxiety disorders in African Americans and lower rates in Hispanics.

THE NEUROBIOLOGY OF THE DISORDER

Genetics

Like most psychiatric disorders, anxiety disorders are complex disorders. Studying anxiety disorders has an advantage over many, as fear and anxiety are common to animals and are easily observed, at least compared to other mental phenomena. Thus, animal models have much informed the research on genetics and other aspects of the disorder. Here, we will, however, concentrate on human studies.

Studies of Inheritance Patterns. A relatively large number of family studies have supported the familial aggregation of the major anxiety disorders, including panic disorder, generalized anxiety disorder, phobias, and agoraphobia. For panic disorder, the familial risk was highest for early-onset panic disorder. In the case of social anxiety disorder, it was strongest for the generalized subtype.

Several large twin studies have demonstrated higher inheritance for monozygotic than dizygotic twins, suggesting a genetic component. The genetic contribution appears to be about 30 percent or more, perhaps as high as 60 percent for the phobias.

Genetic Studies. Among candidate gene studies, linkage studies have had inconsistent results, which is not a surprise, given the assumption that this is a complex disorder. Thus we are unlikely to find highly penetrant genes. Association studies usually rely on candidate genes, usually chosen for their presumed relevance to the disorder or because of prior studies suggesting an association. Most studied are the genes for the neurotransmitter systems and the stress response. Again, the results have been inconsistent.

Genome-wide studies (GWAS) do not require the same a priori assumptions or degree of penetrance. A limitation is the large sample sizes needed, and this limits many of the genetic studies in psychiatry. The most studied has been panic disorder. One study found support for immune-related involvement for the disorder. Another study found two associated single nucleotide polymorphisms (SNPs), a finding later replicated in another study. The genes are involved in mRNA expression in the frontal cortex. Although intriguing, the results remain preliminary. A large research collaboration, the Psychiatric Genetics Consortium, has found several possible novel risk genes; again, these results are tentative.

To date, there is little data on gene–environment interactions, given the substantial sample sizes needed. However, with converging evidence suggesting a role for both cumulative and specific life events, this is an essential area for investigation. There is also limited but compelling evidence for the role of epigenetics in anxiety disorders. However, this area is just emerging.

Neuroimaging Studies

Preclinical data on fear circuitry has guided the search for neuroanatomical associations with anxiety. Thus, the amygdala, and the other components of the frontoamygdala connections (the perirhinal cortex, ventrolateral prefrontal cortex (vlPFC), and anterior insula) have been the most studied. Another focus is the hippocampus, which plays a critical role in fear learning and extinction. Other areas include the posterior and lateral orbitofrontal cortex (OFC), anterior insula, and vlPFC, which show increased neurophysiologic activity in patients with phobias.

[h]Not including PTSD.
[i]Any phobia, including social phobia, specific phobia, and agoraphobia.

Neurochemical systems are also a focus, including central noradrenergic systems, central serotonergic and dopaminergic, and GABA systems.

Studies of fear conditioning in healthy humans are similar to those of animals, confirming that the fear circuitry is conserved across species. The amygdala, ventromedial PFC (vmPFC), and hippocampus have been implicated in both PET and fMRI studies.

Studies of panic disorder suggest that there are abnormalities both when patients are at rest and during an acute panic attack. In the resting state,

hippocampal and parahippocampal areas are implicated, whereas during panic, the associations are in the insular and striatal regions, with reduced activity in other regions such as the PFC. MRI studies also suggest abnormalities of the gray matter volume in the parahippocampal and temporal regions. Also interesting are MRI studies of brain lactate, which suggest an exaggerated response to hypocapnia, suggesting a suffocation response. Receptor-binding studies show abnormalities in GABA and serotonergic, particularly 5-HT$_{1A}$, binding.

Studies in specific phobias suggest activation of anterior paralimbic regions and sensory association cortices related to the particular phobia (be it visual, auditory, or other senses). These suggest hypersensitivity to specific threat-related cues. Also, the amygdala is again implicated.

In social anxiety disorder, functional neuroimaging studies show an exaggerated response to social stimuli, particularly in the medial temporal lobe structures. Most commonly, investigators find amygdala hyperresponsivity to social threats.

Unlike the other disorders, generalized anxiety disorder does not show clear findings of amygdala hyperactivity. The core features are more typical of emotional dysregulation, with disruptions of the functional connections between the anterior cingulate and the amygdala, as well as the uncinate fasciculus. This may suggest weaker frontoamygdala connectivity and fear overgeneralization. Preliminary evidence suggests that effective treatments target these areas, including CBT and pharmacotherapies.

Psychological Studies. Behavioral scientists have helped to elucidate the psychology of fear and anxiety through both animal and human studies. A full discussion of the psychological research is well beyond the scope of this chapter, but most relevant to anxiety disorders are the work of Pavlov and later scientists on the nature of conditioning. In the classic studies, the scientist exposes an animal to an neutral stimulus, such as an auditory tone, and then presents the tone while introducing an aversive stimulus, such as an electric shock. With the repeated pairing of the two stimuli, the neutral stimulus becomes associated with the aversive one, to the point where it alone can elicit the same response even when removing the aversive stimulus. The result is that the animal has been conditioned or learned to fear the neutral stimuli. In behavioral science, the neutral stimulus is called the

conditioned stimulus and the aversive one the unconditioned stimulus. If the scientist presents the conditioned stimulus without the unconditioned one and repeats this often enough, the animal will no longer associate the two stimuli; this is called extinction. How long extinction learning takes will depend on the particular stimuli and the individual animal. It also can depend on context, and a different setting can change the response. Behavioral studies suggest that the animal does not forget the conditioning. Instead, it is now competing with a new memory. Under appropriate circumstances, the pairing, and associated fear response, can be reinstated.

As humans are animals, they experience conditioning and extinction as well. The relevance to anxiety disorders, particularly phobias, should be obvious. Research in conditioning has gone well beyond this simplified description to identify and elaborate the many subtleties of conditioned learning.

ETIOLOGY

Biologic Theories

Neurochemicals and the Fight-or-Flight Reaction. When we perceive stress, our bodies activate certain neurotransmitters and neuropeptides. The result is the "fight-or-flight" reaction. This response is adaptive in specific contexts. However, overgeneralization of their reaction can be disabling and underlies many of the anxiety disorders.

Chronic activation can cause alterations in a variety of systems. Some evidence suggests that early-life stressors can cause this, making us predisposed to anxiety disorders later in life. Why some of us are more susceptible than others, under similar circumstances, is an area of active investigation.

Several neurochemicals and systems are thought to be most relevant to the mechanism between anxiety disorders, including the monoamines, the hypothalamic–pituitary–adrenal (HPA) axis, corticotropin-releasing hormone (CRH) and other chemicals. Broadly put, patients with anxiety disorders have symptoms that suggest an exaggerated noradrenergic system output, along with increased autonomic and sympathetic activation. Table 8-9 summarizes the major neurochemical systems thought to be relevant to anxiety disorders.

Table 8-9

GAD, generalized anxiety disorder; PD, panic disorder; SAD, social anxiety disorder; NMDA, *N*-methyl-D-aspartate; NDRI, norepinephrine–dopamine reuptake inhibitor; SSRI, selective serotonin reuptake inhibitor; SNRI, serotonin–norepinephrine reuptake inhibitor; DCS, D-cycloserine; FAAH, fatty acid amide hydrolase.

Preclinical Studies of Fear Learning. As we mentioned above, the ubiquity of fear and anxiety in many animals makes it relatively easy to study through animal models. Using conditioned models of fear, researchers can study the anatomical correlates of fear anxiety. It is daunting to summarize the many aspects of what we know about the etiology of fear and anxiety. In its broadest sense, one can imagine a stimulus, collected through afferent systems. That stimulus is then processed and evaluated to assess whether it is averse. This assessment involves including previous experiences and environmental contexts associated with the stimulus. What results is a fear or anxiety response, which employs a range of behavioral, endocrine, and autonomic responses to react to that stimulus.

Many areas of the brain and connections between those areas are involved in this response. For example, the amygdala plays a vital role. The amygdala has many subnuclei, called the amygdaloid complex, each with a unique function. The lateral nucleus of the amygdala (LA), for example, is the primary interface for visual, auditory, and somatic sensory information received from the thalamus and cortex. The connections between the thalamus and this nucleus appear to be central to fear conditioning related to these particular stimuli.

Once entering the L.A., it sends the neural representation of the stimulus to various other amygdaloid nuclei. It is then modulated by an array of systems,

including ones that supply context from memory, or about different homeostatic states in the body. Some of the most extensive projections are to the basal (BA) nuclei, which are involved in forming the long-lasting traces for fear conditioning. After much processing, including from other cortical regions, the output nuclei of the amygdala organize the behavioral responses that reflect the sum of the activity of the many nuclei. The central nucleus of the amygdala then outputs this to various motor, autonomic, and neuroendocrine systems involved in expressing fear. This includes the hypothalamus, midbrain, and medulla. For example, the hypothalamus can then activate the CRH to start the associated stress response. The hippocampus, among other structures, also has a critical role in fear learning and extinction and helps in the development of the emotional responses associated with fear.

This discussion is just a brief introduction into what we know and theorize about the neurobiology of anxiety disorders. Our *Comprehensive Textbook of Psychiatry* has a much expanded discussion as well as references to many of the relevant articles. Figure 8-1 summarizes the stages of the fear response, as well as some of the brain regions involved in these stages.

Obsessive-Compulsive and Related Disorders

This chapter includes disorders characterized by repetitive, intrusive thoughts and/or repeated mental acts or behaviors. These disorders include obsessive-compulsive disorder (OCD), body dysmorphic disorder (BDD), hoarding disorder (HD), hair-pulling disorder (trichotillomania), and excoriation (skin-picking) disorder, as well as some related disorders.

THE CLINICAL PRESENTATION

Obsessive-Compulsive Disorder

OCD is a diverse group of symptoms that include intrusive thoughts, rituals, preoccupations, and compulsions. Obsessions are intrusive and unwanted repetitive thoughts, urges, or impulses that often lead to a marked increase in anxiety or distress. Compulsions are repetitive behaviors or mental acts that are done in response to obsessions, or in a rigid, rule-bound way. These recurrent obsessions or compulsions cause severe distress to the person. The obsessions or compulsions are time-consuming and interfere significantly with the person's routine, occupational functioning, usual social activities, or relationships. A patient with OCD may have only obsessions or only compulsions, but in most cases, both obsessions and compulsions are present.

Obsessions and compulsions are the essential features of OCD. An idea or an impulse intrudes itself insistently and persistently into a person's conscious awareness. Typical obsessions associated with OCD include thoughts about contamination ("My hands are dirty") or doubts ("I forgot to turn off the stove").

The typical patterns of OCD symptoms cluster within several limited dimensions, including contamination/cleansing, forbidden thoughts/checking, symmetry/ordering, and hoarding symptoms (see below). Most patients with OCD typically have good insight into the fact that their OCD beliefs are not real. However, some patients have poor insight, and a small number lack any insight—their obsessions are delusional. Such patients may be misdiagnosed with a psychotic disorder and receive inappropriate treatment.

The presentation of obsessions and compulsions is heterogeneous in adults (Table 9-1) and children and adolescents (Table 9-2). The symptoms of an individual patient can overlap and change with time, but OCD has four major symptom patterns, as outlined below.

Contamination/Cleansing. The most common pattern is an obsession of contamination, followed by washing or accompanied by compulsive avoidance of the presumably contaminated object. The feared object is often hard to avoid (e.g., feces, urine, dust, or germs). Patients may rub the skin off their hands by excessive handwashing or may be unable to leave their homes because of fear of germs. Although anxiety is the most common emotional response to the feared object, obsessive shame and disgust are also common. Patients with contamination obsessions usually believe that the contamination is spread from object to object or person to person by the slightest contact.

Pathologic Doubt/Checking. The second most common pattern is an obsession of doubt, followed by compulsions of checking. The obsession often implies some danger of violence (e.g., forgetting to turn off the stove or not locking a door). The checking may involve multiple trips back into the house to check the stove, for example. These patients have obsessional self-doubt and always feel guilty about having forgotten or committed something.

Intrusive/Forbidden Thoughts. In the third most common pattern, there are intrusive obsessional thoughts without a compulsion. Patients usually experience thoughts of a sexual or aggressive act that is reprehensible to the patient. Patients obsessed with thoughts of aggressive or sexual acts may report themselves to the police or confess to a priest. Suicidal ideation may also be obsessive (and unlikely to be acted on), but we should assess for actual risk.

Symmetry/Ordering. The fourth most common pattern is the need for symmetry or precision, which can lead to a compulsion of slowness. Patients can take hours to eat a meal or shave their faces.

Other Symptom Patterns. Religious obsessions and compulsive hoarding are common in patients with OCD. Compulsive hairpulling and nail-biting are behavioral patterns related to OCD. Masturbation may also be compulsive.

Ms. K was referred for psychiatric evaluation by her general practitioner. In the interview, Ms. K described a long history of checking rituals that had caused her to lose several jobs and had damaged numerous relationships. She reported, for example, that she often had the thought that she had not locked the door to the car. It was difficult for her to leave her car until she had repeatedly checked that it was secure. She had broken several car door handles with the vigor of her checking and had been up to an hour late to work because she spent too much time checking her car door.

Similarly, she had recurrent thoughts that she had left the door to her apartment unlocked. She returned several times to check her door before she left for work. She reported that checking doors decreased her anxiety about security. Ms. K reported that she had occasionally tried to leave her car or apartment without checking the door (e.g., when she was already late for work). However, she found that she became so worried that someone would steal her car or break into her apartment that she had difficulty going anywhere. Ms. K reported that her obsessions about security had become so extreme over the past 3 months that she had lost her job due to recurrent tardiness. She recognized the irrational nature of her obsessive concerns but could not bring herself to ignore them. (Courtesy of Erin B. McClure-Tone, Ph.D., and Daniel S. Pine, M.D.)

Body Dysmorphic Disorder

Persons with BDD have persistent preoccupations about one or more perceived defects or flaws in one's appearance. The defects or flaws appear slight or are not observable to others. Their concerns about their appearance result in a range of mental acts or behaviors, including comparing themselves with others, checking in the mirror, or camouflaging their perceived flaws.

The most common concerns (Table 9-3) involve the face and head, particularly those involving specific parts (e.g., the skin, nose shape and size, hair), although symptoms may focus on any area of the body. Sometimes the concern is vague and confusing to understand, such as extreme concern over a "scrunchy" chin. Throughout their illness, patients worry about five to seven different body areas. More than a quarter of patients are concerned with the symmetry of their appearance.

Commonly associated symptoms include ideas or delusions of reference, frequent mirror checking or avoidance of reflective surfaces, and attempts to hide the presumed deformity. The ideas or delusions of reference are usually about others noticing the alleged flaw. The effects on a person's life can be significant, and it is essential to assess for avoidance due to BDD symptoms, which can range from minor social avoidance to being housebound. Patients with BDD have less insight into the truth of their beliefs than those with OCD. Only a quarter of BDD patients have reasonable insight, and around one-third have absent insight.

Table 9-2
Reported Obsessions and Compulsions for 70 Consecutive Child and Adolescent Patients

Major Presenting Symptom	No. (%) Reporting Symptom at Initial Interviewa

Obsession

Concern or disgust with bodily wastes or secretions (urine, stool, saliva), dirt, germs, environmental toxins	30 (43)
Fear something terrible may happen (fire, death or illness of loved one, self, or others)	18 (24)
Concern or need for symmetry, order, or exactness	12 (17)
Scrupulosity (excessive praying or religious concerns out of keeping with patient's background)	9 (13)
Lucky and unlucky numbers	6 (8)
Forbidden or perverse sexual thoughts, images, or impulses	3 (4)
Intrusive nonsense sounds, words, or music	1 (1)

Compulsion

Excessive or ritualized handwashing, showering, bathing, toothbrushing, or grooming	60 (85)
Repeating rituals (e.g., going in and out of door, up and down from chair)	36 (51)
Checking doors, locks, stove, appliances, car brakes	32 (46)
Cleaning and other rituals to remove contact with contaminants	16 (23)
Touching	14 (20)
Ordering and arranging	12 (17)

Measures to prevent harm to self or others (e.g., hanging clothes a certain way)	11 (16)
Counting	13 (18)
Hoarding and collecting	8 (11)
Miscellaneous rituals (e.g., licking, spitting, special dress pattern)	18 (26)

[a]Multiple symptoms recorded, so total exceeds 70.

From Rapoport JL. The neurobiology of obsessive-compulsive disorder. *JAMA*. 1988;260:2889, with permission.

Ms. R, a 28-year-old single woman, presented with the complaint that she is "ugly" and that she feels others are laughing at her, despite family telling her she was attractive. She first became preoccupied with her appearance when she was 13. She became obsessed with her "facial defects," feeling, for example, that her nose was fat, or her eyes were too far apart. Up until this point, Ms. R was confident, a good student, and socially active. However, her fixation on her face caused her to withdraw socially and have difficulty concentrating in school, which in turn hurt her grades.

Ms. R dropped out of high school and went for her GED due to her preoccupation. She began to frequently pick at "blemishes" and hairs on her face. She frequently checked herself in mirrors and other reflective surfaces (e.g., spoons, windows), and found herself thinking about her defects almost daily. Her family and others could not convince her that there was nothing wrong with her appearance.

Table 9-3
Location of Imagined Defects in 30 Patients with Body Dysmorphic Disorder[a]

Location	N	%
Hair[b]	19	63

Nose	15	50
Skin[c]	15	50
Eyes	8	27
Head, face[d]	6	20
Overall body build, bone structure	6	20
Lips	5	17
Chin	5	17
Stomach, waist	5	17
Teeth	4	13
Legs, knees	4	13
Breasts, pectoral muscles	3	10
Ugly face (general)	3	10
Ears	2	7
Cheeks	2	7
Buttocks	2	7
Penis	2	7
Arms, wrists	2	7
Neck	1	3
Forehead	1	3
Facial muscles	1	3
Shoulders	1	3
Hips	1	3

[a]Total is greater than 100% because most patients had "defects" in more than one location.
[b]Involved head hair in 15 cases, beard growth in 2 cases, and other body hair in 3 cases.
[c]Involved acne in 7 cases, facial lines in 3 cases, and other skin concerns in 7 cases.

Hoarding Disorder

Persons with HD have persistent and profound difficulty discarding or parting with their possessions. The disorder leads to significant congestion and clutter and substantive distress or impairment, differentiating it from regular collecting. Compulsive hoarding is a common and often disabling phenomenon associated with impairment in such functions as eating, sleeping, and grooming. Hoarding may result in health problems and poor sanitation, particularly when hoarding of animals is involved. It may also lead to injuries from fire or falling. As a rule, people with the disorder acquire things of little or no value and cannot throw them away.

What drives the behavior appears to be the fear of losing items that the patient believes will be needed later and a distorted belief about or an emotional attachment to possessions. Most hoarders do not perceive their behavior to be a problem. Many perceive their behavior to be reasonable and part of their identity. Most hoarding patients accumulate possessions passively rather than intentionally, thus clutter accumulates gradually. Commonly hoarded items include newspapers, mail, magazines, old clothes, bags, books, lists, and notes. Hoarding poses risks to not only the patient but also to those around them. Clutter accumulated from hoarding has caused deaths from fire or other accidents. It can also attract pest infestations that can pose a health risk both to the patient and residents around them. Many sufferers have been evicted from their homes or threatened with eviction as a result of their hoarding. In severe cases, hoarding can interfere with work, social interaction, and necessary activities such as eating or sleeping.

The pathologic nature of hoarding comes from the inability to organize possessions and keep them organized. Many patients hoard rather than make decisions about discarding items. Patients with HD also overemphasize the importance of recalling information and possessions. For example, a hoarder will keep old newspapers and magazines because they believe that important information may be lost. Patients may believe that forgetting the information will lead to severe consequences and prefer to keep their possessions within sight so as not to forget them.

Ms. T, a 55-year-old single woman, presented to a therapist accompanied by her adult son, who expressed concern about Ms. T's inability to "throw things away." He reported that Ms. T's home was extremely cluttered with "needless things." Whenever he attempted to help her "organize things," however, Ms. T would become agitated and argumentative. Ms. T confirmed her son's complaint and reported having this difficulty for as long as she could remember, but never really viewed it as a problem.

Over the past 5 years, Ms. T's home had become increasingly cluttered to the point that it became more and more challenging to move around within it. She was able to keep the kitchen and bathroom relatively clutter-free. However, boxes and bags filled with papers, magazines, clothes, and miscellaneous gifts and trinkets filled the rest of her home. Her living room was the most affected. Her son could no longer visit his mother as so uncomfortable at her home. Ms. T admits that his avoidance of her home has been a significant source of depression for her. Ms. T had enjoyed entertaining her family and friends but had not done so in years as she felt that her home was no longer suitable. She had made a few attempts to clean out her home but was unable to discard most items. When asked why she was keeping them, she replied, "I may need them later."

Hair-Pulling Disorder (Trichotillomania)

Hair-pulling disorder is a chronic disorder characterized by repetitive hairpulling, leading to variable hair loss that may be visible to others. It is also known as *trichotillomania*, from the Greek *trich* (hair) and *tillein* (to pull or pluck), a term coined by a French dermatologist Francois Hallopeau in 1889. Although once considered rare, it appears to be relatively common. It resembles both obsessive-compulsive and impulse control disorder: increased tension before the hairpulling leads to the behavior and then subsequent relief or satisfaction.

Hair-pulling disorder, or trichotillomania, is characterized by pulling out one's hair. The pulling is not for cosmetic reasons, but instead, individuals often describe an irresistible urge to pull out their hair. This hairpulling

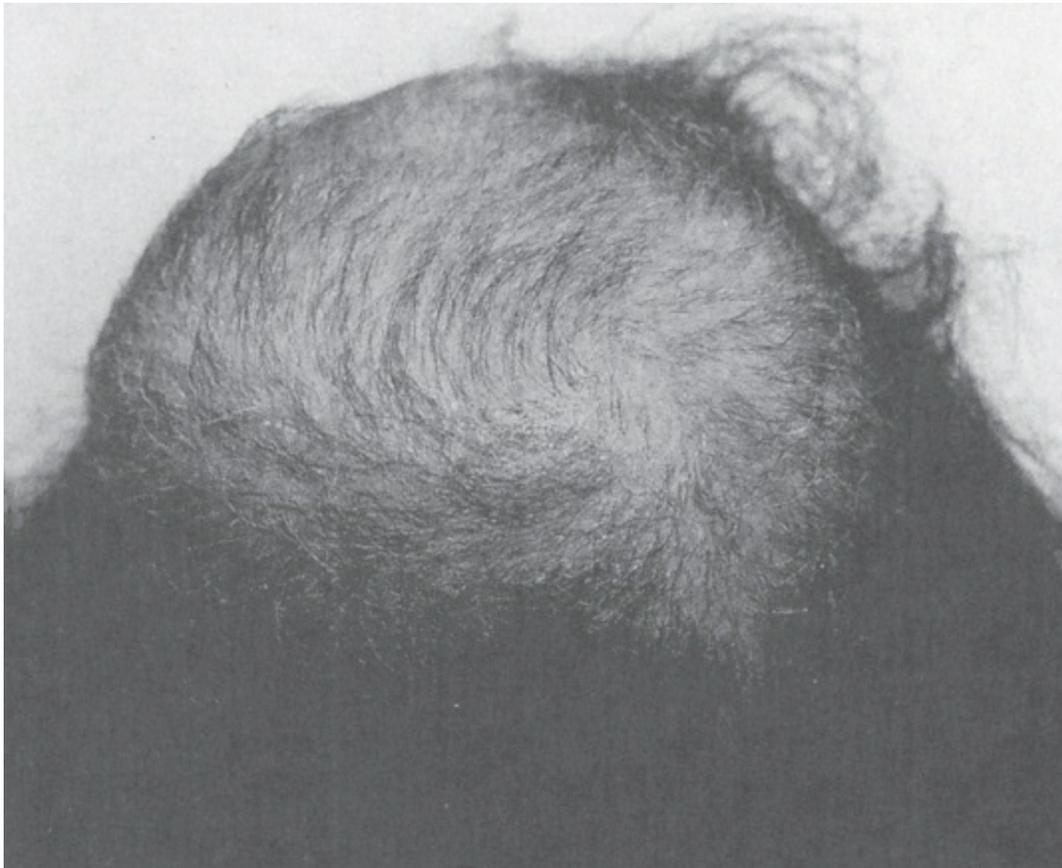
results in noticeable hair loss and is associated with repeated attempts to decrease or stop hairpulling. Patients with hair-pulling disorder may experience an increasing sense of tension before engaging in the behavior and achieve a sense of release or gratification from pulling out their hair. All areas of the body may be affected, most commonly the scalp (Fig. 9-1). Other areas involved are eyebrows, eyelashes, and beard; trunk, armpits, and pubic areas are less commonly involved.


FIGURE 9-1
Hair-pulling disorder (trichotillomania). Note the typical findings of an area of incomplete alopecia involving the frontal and vertex scalp. (From Sadock BJ, Sadock VA, Ruiz P, eds. *Kaplan & Sadock's Comprehensive Textbook of Psychiatry*. 9th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2009, with permission.)

There are (at least) two types of hairpulling. *Focused pulling* is the use of an intentional act to control unpleasant personal experiences, such as an urge, bodily sensation (e.g., itching or burning), or thought. In contrast, *automatic pulling* occurs outside the person's awareness and, most often, during

sedentary activities. Most patients have a combination of these types.

The hair loss usually appears as short, broken strands near long, healthy hairs in the affected areas. No abnormalities of the skin or scalp are present. The hairpulling is usually painful, although pruritus and tingling may occur in the affected area. *Trichophagy,* mouthing of the hair, may follow the hair plucking. Complications of trichophagy include trichobezoars, malnutrition, and intestinal obstruction. Patients usually deny the behavior and often try to hide the resultant alopecia. The patients may also self-mutilate in other ways, such as headbanging, nail-biting, scratching, gnawing, or excoriation.

Ms. C, a 27-year-old single woman, came to a local clinic complaining of persistent hairpulling. She first started at age 11 when she began to pick the hairs at the nape of her neck. She would persistently pick at the hair until there was almost none left. Fortunately, her hair was long, so no one noticed the lack of hair at the back of her neck. Over the years, her hair picking progressed until she began picking hair from her entire head, leaving noticeable small bald patches. She strategically hid the bald patches by brushing over the remainder of her hair or with carefully placed scarves and hats. Despite her habit, Ms. C's daily functioning was average. She earned good grades in school and was a year away from getting her master's degree.

Ms. C's habit was constant, occurring every day, often without her noticing it. She could only be reading an assignment for school, and eventually, her hand would find its way into her hair to find hair to pull. Soon she would notice a small pile of hairs in her book or on her lap, indicating that she had been pulling her hair out for a while. Whenever she tried to stop herself from pulling her hair, she would become increasingly nervous and anxious until she resumed the hairpulling. Her hair-pulling sessions lasted anywhere from 10 minutes to an hour.

Excoriation (Skin-Picking) Disorder

People with excoriation disorder repeatedly pick their skin, sufficiently to cause lesions. Individuals with skin-pulling attempt to decrease or stop skin-picking; however, they are unable to do so. While some picking of scabs is

likely universal, in the case of excoriation disorder, the behavior causes clinically significant distress or impairment. The historical literature describes cases of "neurotic excoriation" or "psychogenic excoriation," however, it was only with *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) that the disorder became a separate diagnosis.

Skin-picking may be from any area of the body but is most commonly from the face, followed by the hands, fingers, arms, and legs (Fig. 9-2). Patients may pick from multiple sites. In severe cases, skin-picking can result in physical disfigurement and medical consequences that require medical or surgical interventions (e.g., skin grafts or radiosurgery).

Patients may experience tension before picking and relief or gratification after picking. Patients may pick to relieve stress, tension, and other negative feelings. Despite the feeling of relief felt from picking, patients often feel guilty or embarrassed at their behavior. Up to 87 percent of patients report feeling embarrassed by the picking and 58 percent report avoiding social situations. Many patients use bandages, makeup, or clothing to hide their picking. Of skin-picking patients, 15 percent report suicidal ideation due to their behavior, and about 12 percent have attempted suicide.

Ms. J, a 22-year-old single woman, presented to a psychiatrist at the urging of her dermatologist because of compulsively picking her facial skin. She picked at it every day up to three times a day in sessions lasting from 20 minutes to over an hour. She had massive scarring and lesions on her face. She went to a physician 6 months prior when one of the lesions had become infected.

Ms. J began picking her face at age 11 at the onset of puberty. At first, she only picked at acne that formed on her face, but as the urge to pick became greater, she started picking at clear patches of skin as well. Due to the scaring and lesions, Ms. J became increasingly withdrawn and avoided all social engagements. She reported feeling great tension before picking, and only felt relief after she began picking.

Skin-picking disorder. Multiple erythematous and pigmented maculae and crusted erosions on chin. (From Sadock BJ, Sadock VA, Ruiz P. *Kaplan & Sadock's Comprehensive Textbook of Psychiatry*. 9th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2009, with permission.)

Obsessive-Compulsive or Related Disorder due to Another Medical Condition

As with most psychiatric disorders, when OCD (or another disorder in this category) is due to some other medical condition, we use a different diagnosis. We include a discussion of medical causes of obsessive and compulsive symptoms in our section on differential diagnosis.

Substance-Induced Obsessive-Compulsive or Related Disorder

Sometimes the symptoms described in this chapter may be due to a substance, including drugs, medications, and alcohol (either during use or during withdrawal), and is not part of a delirium. In such cases, we would use this separate diagnosis.

Other Specified Obsessive-Compulsive or Related Disorder

This category is for patients who have symptoms characteristic of obsessive-compulsive and related disorder but do not meet the full criteria for any specific obsessive-compulsive or related disorder. This diagnosis is appropriate under three situations: (1) an atypical presentation, (2) another specific syndrome not listed in DSM-5 (such as Olfactory Reference Syndrome, described next), and (3) the information presented is insufficient to make a full diagnosis of an obsessive-compulsive or related disorder.

Olfactory Reference Syndrome. People with olfactory reference syndrome have a false belief that they have a foul body odor that is not perceived by others. The preoccupation leads to repetitive behaviors such as washing the body or changing clothes. Patients with the disorder may have good, fair, poor, or absent insight into the behavior. The syndrome is predominant in males and single persons. The mean age of onset is 25 years of age. The belief of a subjective sense of smell that does not exist externally may rise to the level of a somatic delusion, in which a diagnosis of a delusional disorder may be more appropriate. The syndrome has been frequently described in the psychiatric literature, usually classified as a delusion of perception. Whether or not it deserves a unique diagnosis remains controversial.

In assessing a patient with olfactory reference syndrome, it is essential to exclude other medical causes. Some patients with temporal lobe epilepsy may complain of smelling foul odors. Local irritations of the hippocampus from pituitary tumors may also cause olfactory sensations. Patients with inflammation of the frontal, ethmoidal, or sphenoidal sinuses may also have a subjective sense of offensive odors. DSM-5 includes olfactory reference syndrome in the "other specified" designation for the obsessive-compulsive and related disorder of DSM-5.

DIAGNOSIS

Obsessive-Compulsive Disorder

Table 9-4 lists the diagnostic approaches to OCD in DSM-5 and ICD-10. We can usually diagnose OCD with a thorough psychiatric history and

examination. Patients often attempt to neutralize obsessions with compulsions. These compulsions are usually not credibly connected to the thoughts, or they are excessive. When assessing the negative impact of OCD symptoms, it is important also to address avoidance of triggers of obsessions and compulsions.

Body Dysmorphic Disorder

Table 9-5 lists the diagnostic approaches to BDD in DSM-5 and ICD-10. The DSM-5 diagnostic criteria for BDD stipulate preoccupation with a perceived defect in appearance or overemphasis of a slight defect. It also requires that at some point during the disorder, the patient has compulsive behaviors or mental acts related to the preoccupation. These compulsions may include mirror checking, excessive grooming, or comparing their appearance to that of others. The preoccupation causes patients significant emotional distress or markedly impairs their ability to function in important areas.

Hoarding Disorder

Table 9-6 lists the diagnostic approaches to HD in DSM-5 and ICD-10. We diagnose HD using the significant features of the disorder: patients acquire large amounts of useless or valueless possessions, they cannot throw them away, and this leads to significant clutter in living areas. If their space is not cluttered, it is because others have stepped in to clean it. Finally, it should cause significant distress or functional impairment. The fifth edition of the DSM-5 includes diagnostic specifiers that relate to insight, which may be rated poor, fair, or good. Some patients are completely unaware of the full extent of the problem and resistant to treatment. At times, delusional beliefs about hoarded items are present.

Hair-Pulling Disorder (Trichotillomania)

Table 9-7 lists the diagnostic approaches to hair-pulling disorder in DSM-5 and ICD-10. It emphasizes the repetitive and compulsive nature of the behavior as well as the fact that it is not motivated by cosmetic reasons.

Excoriation (Skin-Picking) Disorder

Table 9-8 lists the diagnostic approaches to excoriation (skin-picking)

disorder in DSM-5 and ICD-10. DSM-5 diagnostic criteria for skin-picking disorder require recurrent skin-picking resulting in skin lesions and repeated attempts to decrease or stop picking. The skin-picking must cause clinically relevant distress or impairment in functioning. The skin-picking behavior cannot be attributed to another medical or mental condition and cannot be a result of a substance use disorder (e.g., cocaine or methamphetamine use). A thorough physical examination is crucial before a psychiatric diagnosis.

DIFFERENTIAL DIAGNOSIS

Medical Conditions

Several primary medical disorders can produce syndromes bearing a striking resemblance to OCD.

OCD-like symptoms have been reported in children following group A beta-hemolytic streptococcal infection and have been called *pediatric autoimmune neuropsychiatric disorders associated with streptococcus* (PANDAS). They may result from an autoimmune process that leads to inflammation of the basal ganglia that disrupts cortical–striatal–thalamic axis functioning.

The current conceptualization of OCD as a disorder of the basal ganglia derives from the phenomenologic similarity between idiopathic OCD and OCD-like disorders that are associated with basal ganglia diseases, such as Sydenham chorea and Huntington disease. It is essential to search for the neurologic signs of these disorders when assessing a patient with presumed OCD. Also, OCD often develops before age 30 years, and new-onset OCD in an older individual should raise questions about potential neurologic contributions to the disorder.

Table 9-4
Obsessive-Compulsive Disorder

Disorder	Obsessive-Compulsive Disorder	
	DSM-5	**ICD-10**
Diagnostic name	Obsessive-Compulsive Disorder	Obsessive-Compulsive Disorder

Symptoms	1. Obsessions (Intrusive thoughts that accompany behaviors and that individuals may attempt to ignore or counteract through action)
	2. Compulsions (repetitive actions, commonly driven by an obsessive thought, performed to relieve anxiety or fear)
		• Recurrent obsessional thoughts and/or compulsive acts
		  • Obsessions: ideas, images, or impulses occurring recurrently
		  • Compulsions: repeated stereotyped behaviors meant to neutralize a thought/anxiety or prevent a perceived adverse event
		• Attempts at resisting thoughts and behaviors are frequently unsuccessful and cause worsening anxiety

Required number of symptoms	Obsessive thoughts, compulsions, or both	Presence of obsessions, compulsions, or both
Psychosocial consequences of symptoms	Symptoms and behaviors consume at least 1 hr/day or cause significant distress and impairment	

Exclusions (not result of):	Medical illness Substance Other psychiatric disorder	Obsessive-compulsive personality disorder
Symptom specifiers	**Tic related** • current or prior tic disorder **With good or fair insight** • understanding that beliefs surrounding actions may not be true **With poor insight** • feeling that beliefs surrounding actions are likely true **With absent insight and/or delusional beliefs** • strong conviction that beliefs surrounding actions are true	• Predominantly obsessional thoughts or ruminations • Predominantly compulsive acts (obsessional rituals) • Mixed obsessional thoughts and acts
Severity specifiers	With or without insight (per above)	

Many medical disorders can cause alopecia. A biopsy may be necessary to distinguish hair-pulling disorder from alopecia areata and tinea capitis.

Many dermatologic conditions can cause skin-picking. Conditions associated with itching (such as scabies) can cause picking, as well as other medical conditions (such as in Prader–Willi syndrome).

Tourette Disorder. OCD is closely related to Tourette disorder, as the two conditions frequently co-occur, both in individuals over time and within families. About 90 percent of persons with Tourette disorder have compulsive symptoms, and as many as two-thirds meet the diagnostic criteria for OCD.

Classically, patients with Tourette disorder have recurrent vocal and motor tics that bear only a slight resemblance to OCD. The premonitory urges that precede tics often strikingly resemble obsessions, however, and many of the more complicated motor tics are very similar to compulsions.

Other Psychiatric Conditions

Many other psychiatric disorders include obsessive-compulsive symptoms, and we must also rule out these conditions when diagnosing OCD. OCD exhibits a superficial resemblance to obsessive-compulsive personality disorder, which is associated with an obsessive concern for details, perfectionism, and other similar personality traits. However, only OCD is associated with genuine obsessions and compulsions. Worries in generalized anxiety disorder are about real-life concerns, and they tend to be less irrational and ego-dystonic than in OCD. Similarly, the ruminations of depression and preoccupations of mania are typically mood-congruent and ego-syntonic; in neither case are symptoms neutralized by compulsions.

Psychotic symptoms often lead to obsessive thoughts and compulsive behaviors, bodily preoccupations, or hoarding behaviors that can be difficult to distinguish from the obsessive-compulsive and related disorder. Patients with psychotic disorders, however, cannot acknowledge the unreasonableness of their behavior. Also, psychotic patients typically have a host of other features that are not characteristic of OCD.

In some patients with BDD, their preoccupations have a delusional intensity. In such cases, delusional disorder, somatic type can be made, generally in addition to BDD, to capture the true nature of the patient's presentation.

Table 9-5
Body Dysmorphic Disorder

Body Dysmorphic Disorder

Disorder	DSM-5	ICD-10
Diagnostic name	Body Dysmorphic Disorder	Body Dysmorphic Disorder
Symptoms	1. Preoccupation with physical appearance and subjective flaws 2. Presence of repetitive behaviors at some point during the disorder • Checking • Grooming • Skin-picking • Recurrent thoughts/perseveration on comparing physical appearance to that of others	Excessive preoccupation with image or appearance
Required number of symptoms	Both of the above, causing significant impairment and/or distress and excluding other causes of symptoms	
Psychosocial consequences of symptoms	Symptoms and behaviors cause significant distress and impairment	Significant distress or impairment in areas of functioning
Exclusions (not result of):	Medical illness Substance Eating disorder Other psychiatric disorder	

Symptom specifiers	**With muscle dysmorphia** • preoccupation with perceived low muscle mass or small body build **With good or fair insight** • understanding that beliefs may not be true **With poor insight** • feeling that beliefs are likely true **With absent insight and/or delusional beliefs** • strong conviction that beliefs are true
Severity specifiers	With or without insight (per above)

Similarly, major depression is often associated with obsessive thoughts that, at times, border on actual obsessions. However, in the case of major depression, the obsessive symptoms are only found during a depressive episode.

Individuals with an avoidant personality disorder or social phobia may worry about being embarrassed by imagined or real defects in appearance. However, this concern is usually not prominent, persistent, distressing, or impairing.

Other psychiatric disorders may cause hoarding symptoms, including autism spectrum disorders (where collections may reflect a specific interest) and psychotic disorders. We should only diagnose HD if the hoarding symptoms are independent of these other disorders.

Neurodevelopmental and neurodegenerative conditions may be associated with hoarding. For example, in Prader–Willi Syndrome, individuals are characterized by hoarding of food, obesity, and skin-picking. Alzheimer disease is another example. Damage to specific brain regions (anterior ventromedial prefrontal and cingulate cortices) may cause excessive and

indiscriminate hoarding activity.

Patients with anorexia nervosa have a bodily preoccupation, but the focus is on weight. In gender dysphoria, it is a discomfort with, or a sense of wrongness about, one's primary and secondary sex characteristics. In major depressive disorder, there may be mood-congruent cognitions involving appearance that occur exclusively during a major depressive episode.

Olfactory reference syndrome may result in other compulsive or repetitive behaviors such as washing or changing one's clothes. Individuals with BDD have obsessional preoccupations about their appearance and may have associated compulsive behaviors (e.g., mirror checking). We should only include multiple diagnoses when the specific focus of concerns of the obsessions extends beyond the usual focus of that disorder.

Some patients with OCD may hoard as a response to an unwanted obsession. This situation is most familiar with obsessions around symmetry, incompleteness, or fears of harm or contamination (e.g., keeping an object in case discarding that object leads to harm). In contrast, in HD, there is no associated obsession; instead, the individual wishes to retain saved items and is distressed by the thought of discarding them. In some cases, both OCD and HD may be comorbid. Skin-picking may also occur in response to obsessions about contamination. Skin-picking is also common in BDD, but in these individuals, it is a response to concerns about body appearance, and a second diagnosis is not necessary.

Patients with factitious dermatitis or *dermatitis artefacta* pick their skin as a type of self-inflicted injury and use more elaborate methods than simple excoriation to self-induce skin lesions. It is seen in 0.3 percent of dermatology patients and has a female:male ratio of 8:1. It can present at any age but occurs most frequently in adolescents and young adults. It may include a variety of skin lesions, such as blisters, ulcers, erythema, edema, purpura, and sinuses. The morphology of factitious dermatitis lesions is often bizarre and linear, with clear-cut, angulated, or geometric edges. The presence of entirely healthy, unaffected skin adjacent to the horrific-looking lesions is a clue to the diagnosis of factitious dermatitis (Fig. 9-3). Also, the patient's description of the history of the lesions is usually vague and lacks detail about the appearance and evolution of the lesions.

Table 9-6
Hoarding Disorder

	Hoarding Disorder	
Disorder	**DSM-5**	**ICD-10**
Diagnostic name	Hoarding Disorder	Hoarding Disorder
Symptoms	1. Excessive attachment to possessions 2. Distress related to being separated from items 3. Excessive accumulation of possessions 4. Accumulation results in significant distress, impairment, and/or safety/health compromise	• Difficulty parting with objects due to perceived need to save possessions • Distress and functional impairment associated with being separated from possessions
Required number of symptoms	All of the above	
Psychosocial consequences of symptoms	Symptoms and behaviors cause significant distress and impairment	Symptoms and behaviors cause significant distress and impairment
Exclusions (not result of):	Medical illness Neurocognitive disorder Other psychiatric disorder	
Symptom specifiers	**With excessive acquisition** • hoarding	

	accompanied by excessive acquisition of additional possessions
	With good or fair insight
	• understanding that actions are problematic
	With poor insight
	• belief that actions may not be problematic
	With absent insight and/or delusional beliefs
	• strong conviction that actions are not problematic
Severity specifiers	**With or without insight (per above)**

Normal Behaviors

Certain normal behaviors can become more prominent in specific individuals without being a disorder. We live in a society concerned with appearance; some persons are more concerned than others. Some of us are more careful about avoiding contamination or germs and may wash or avoid touching potentially infected persons or items. Living during a global pandemic naturally blurs the line between contamination phobia and understandable caution. We expect this overlap between pathologic and prudent to continue long after the pandemic. Many of us occasionally remove stray hair, often for cosmetic reasons. We may bite at a fingernail or pick at a scab. Collecting is an enjoyable and sometimes lucrative hobby for many people.

Table 9-7
Hair-Pulling Disorder (Trichotillomania)

	Trichotillomania	
Disorder	**DSM-5**	**ICD-10**
Diagnostic name	Trichotillomania (Hair-Pulling Disorder)	Trichotillomania
Symptoms	1. Recurrent hairpulling causing hair loss 2. Hairpulling despite repeated attempts to change/end behaviors 3. Actions cause distress and/or impaired functioning	• Presence of noticeable hair loss due to recurrent hairpulling • Hair-pulling behavior preceded by increased anxiety that is relieved by hairpulling
Required number of symptoms	All of the above	
Psychosocial consequences of symptoms	Symptoms and behaviors cause significant distress and impairment	
Exclusions (not result of):	Medical illness Other psychiatric disorder	Pre-existing inflammation of skin Response to delusion or hallucination Stereotyped movement disorder

Table 9-8
Excoriation (Skin-Picking)

| | Excoriation Disorder | |
Disorder	DSM-5	ICD-10
Diagnostic name	Excoriation (Skin-Picking) Disorder	Excoriation (Skin-Picking) Disorder
Symptoms	1. Recurrent skin-picking causing lesions to the skin 2. Ongoing skin-picking despite repeated attempts to change/end behaviors 3. Actions cause distress and/or impaired functioning	See criteria for obsessive-compulsive disorders
Required number of symptoms	All of the above	
Psychosocial consequences of symptoms	Symptoms and behaviors cause significant distress and impairment	
Exclusions (not result of):	Other psychiatric disorder	Factitious dermatitis

In each case, the behavior is desired, usually restricted (e.g., a collector may only collect certain toys) and often enjoyable. These disorders, however, represent impulsive behaviors that cause distress and impairment.

COMORBIDITY

Obsessive-Compulsive Disorder

Persons with OCD are commonly affected by other mental disorders. The lifetime prevalence for major depressive disorder in persons with OCD is

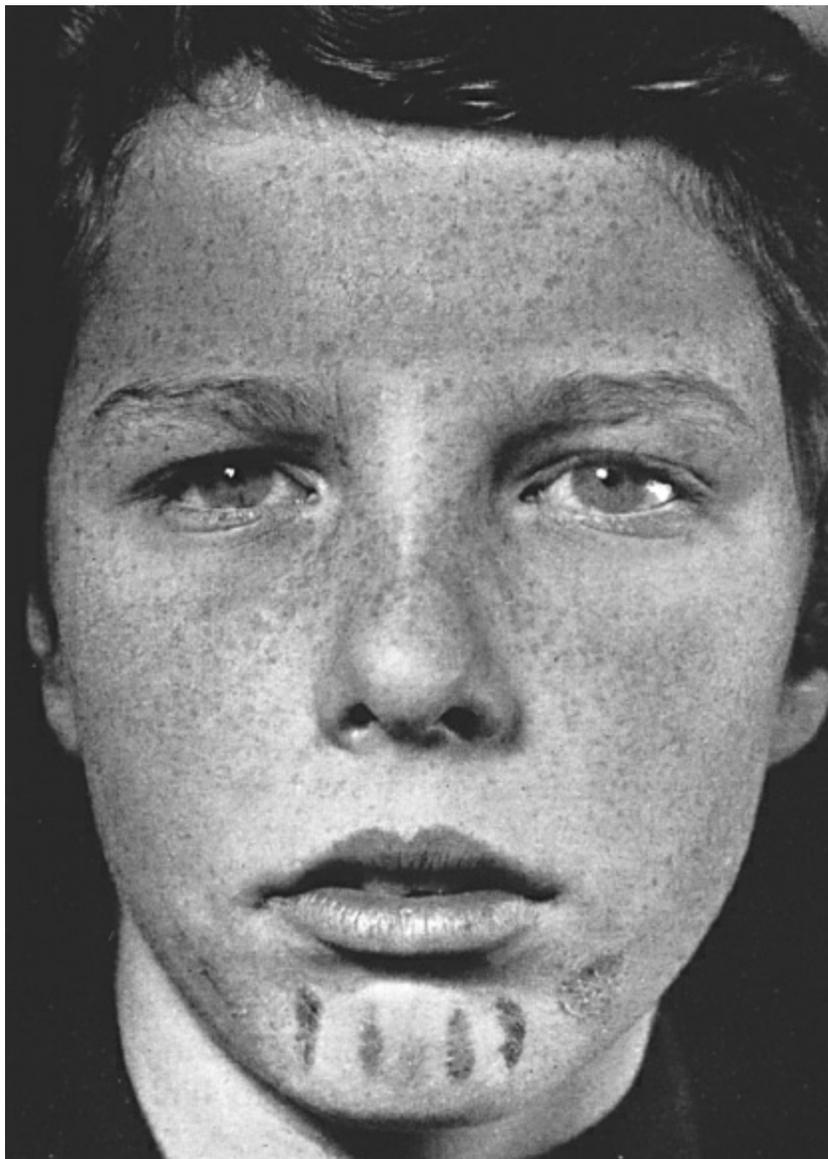
about 67 percent and for social phobia about 25 percent. Suicide is a risk for all patients with OCD. Other common comorbid psychiatric diagnoses in patients with OCD include alcohol use disorders, generalized anxiety disorder, specific phobia, panic disorder, eating disorders, and personality disorders. OCD exhibits a superficial resemblance to obsessive-compulsive personality disorder, which is associated with an obsessive concern for details, perfectionism, and other similar personality traits. The incidence of Tourette disorder in patients with OCD is 5 to 7 percent, and 20 to 30 percent of patients with OCD have a history of tics.


FIGURE 9-3
Typical self-produced lesions with scabbing. (From Douthwaite AH, ed. *French's*

Body Dysmorphic Disorder

Of the various obsessive-compulsive and related disorders, it appears that BDD is the one most associated with comorbid depression with a lifetime rate of 75 percent, as well as with suicidality, with 80 percent having experienced suicidal ideation. About one-third of BDD patients have a lifetime history of OCD, and around 30 percent of BDD patients experience panic attacks triggered by appearance concerns. BDD is also associated with high levels of rejection sensitivity and low self-esteem. Many patients with BDD use substances to self-medicate symptoms of social anxiety or emotional pain.

Hoarding Disorder

Comorbid OCD is common in patients with HD. Other prevalent comorbid disorders include generalized anxiety disorder and major depressive disorder.

Hair-Pulling Disorder

Comorbid conditions include other body-focused repetitive behavior disorders, with excoriation disorder the most common. OCD is also more prevalent in hair-pulling disorder than in the general population. More than half of treatment-seeking individuals with hair-pulling disorder have a comorbid psychiatric disorder, with mood and anxiety disorders the most common. Also, hair-pulling disorder can result in medical sequelae (e.g., trichobezoars) and decreased quality of life.

Excoriation Disorder

Comorbid conditions in excoriation disorder include other body-focused repetitive behavior disorders, with hair-pulling disorder the most common. OCD and BDD are also more prevalent in excoriation disorder than in the general population. Other common comorbid psychiatric disorders in excoriation disorder include mood and anxiety disorders.

COURSE AND PROGNOSIS

Obsessive-Compulsive Disorder

The course of OCD is generally chronic, and in the absence of intervention, symptoms may persist for decades. Nevertheless, recent data emphasize that long-term outcomes can be positive. Thus, patients should be encouraged to remain hopeful and to try a range of different evidence-based treatments.

Body Dysmorphic Disorder

The course of BDD is generally chronic, and in the absence of intervention, symptoms may persist for decades. Earlier age of onset and more severe symptoms at intake may predict a worse course.

Hoarding Disorder

HD has a somewhat later course than most obsessive-compulsive and related disorders. In the absence of intervention, its course appears to be often chronic and progressive. Hoarding symptoms often begin in childhood and adolescence, with diagnostic criteria met only in the 30s, and worsening of symptoms in each subsequent decade.

Hair-Pulling Disorder

There are relatively little data on the long-term course of hair-pulling disorder. In the absence of intervention, its course is likely often chronic. However, some data indicate that in a proportion of cases, remission does occur.

Excoriation Disorder

Those data which exist on the long-term course of excoriation disorder suggest that, without intervention, this is often chronic, albeit with fluctuations in severity over time. As is the case in other obsessive-compulsive and related disorders, individuals often report that they have not sought medical attention because they are embarrassed by their symptoms, feel that they should stop the symptoms by themselves, or because they are unaware that the symptoms may be part of a known condition or that there are efficacious treatments.

TREATMENT

Obsessive-Compulsive Disorder

Pharmacotherapy. Effective medications include clomipramine and selective serotonin reuptake inhibitors (SSRIs, which, along with clomipramine and other serotonergic medications, are sometimes called serotonin reuptake inhibitor [SRIs]). Head-to-head comparisons of clomipramine and SSRIs show equal efficacy but better tolerability of the SSRIs. In general, clinicians must use higher doses to achieve an optimal effect. Examples are doses of 80 mg of fluoxetine or 200 mg of sertraline. Some patients respond to even higher doses. Exceeding the recommended doses is not, however, advisable for clomipramine or citalopram, due to safety concerns. There is also some evidence that response to SRIs is slower in OCD than in depression; clinicians are therefore encouraged to prescribe an SRI for at least 12 weeks before deciding to switch agents or augment with another psychotropic. A general rule of thumb is that we should continue to use the dose that was required to obtain a response for at least 1 to 2 years. When discontinuing medication, there is a real risk of relapse, so this should be done very gradually, with small adjustments made every few months.

Patients who fail to respond to one SRI may respond to another.

The most extensive evidence base is for antipsychotics in adult OCD. Among those, risperidone and aripiprazole are best supported as adjuncts. Some studies have indicated that these are particularly useful in patients with tics, but not all data are consistent. When a response to these agents occurs, it typically happens relatively quickly (e.g., 4 weeks). When using dopamine receptor blockers, it is crucial to monitor adverse events.

Memantine, riluzole, ketamine, lamotrigine, and *N*-acetylcysteine (NAC) are other promising augmentation agents.

Psychotherapy. There is a long history of understanding OCD symptoms from a psychodynamic perspective, but there is no rigorous evidence that a psychodynamic approach is useful in the treatment of OCD. Instead, empirical research on the psychotherapy of OCD has emerged from behavioral and cognitive perspectives. Exposure and response prevention

(ERP) has proven to be a particularly effective component of treatment, with more recent work also focusing on the potential role for cognitive and mindfulness approaches. The essential principle of ERP is to minimize avoidance of distressing cues, and instead to encourage in vivo exposure to feared situations and imaginal exposure to feared consequences. After such exposures, it is important not to engage in the usual compulsive response. The therapist and patient then develop a hierarchy of gradual exposure to more distressing cues and follow it. As in the case of pharmacotherapy, it is essential to ensure that the dose and duration of ERP are sufficient.

Other cognitive approaches to OCD focus on thought distortions (e.g., inflated responsibility). The therapist and patient collaborate to test such distortions and replace them with more adaptive thinking patterns. More recently, mindfulness techniques have supplemented these approaches. Family sessions may also be helpful, particularly with younger patients, to better understand OCD and the principles of ERP.

Combined Treatment. Clinical guidelines indicate that either pharmacotherapy or psychotherapy is a reasonable first-line intervention for the management of OCD. In younger patients, it seems reasonable to begin cognitive-behavioral therapy (CBT) first. In patients with more severe symptoms or comorbid depression, it seems reasonable to begin pharmacotherapy first. There is some evidence that the combination of CBT and pharmacotherapy is particularly useful.

Other Somatic Therapies. Targeted neurosurgical lesions to cortico-striatal-thalamic-cortical (CSTC) tracts have been shown efficacious in a proportion of highly treatment-refractory patients. Approaches have included anterior cingulotomy and capsulotomy, among other techniques. The more recent focus on neurosurgical work has been on deep brain stimulation, with implantation of electrodes to stimulate specific brain regions. Transcranial magnetic stimulation has also been studied for OCD, although data are not yet sufficiently strong to motivate for routine clinical use. Electroconvulsive therapy does not seem to be useful for OCD.

Body Dysmorphic Disorder

SSRIs are efficacious in the treatment of BDD, including delusional BDD.

There is some evidence that, as in the case of OCD, doses higher than those ordinarily used in the treatment of depression are beneficial in BDD, as are longer durations. Again, the duration of treatment should be longer, with gradual tapering of dosage and close monitoring of emergent symptoms.

Patients who do not respond to one SRI may respond to another. There is anecdotal evidence that buspirone augmentation of SRIs is useful in partial responders. There is little controlled data on using dopamine receptor blockers as augmenting agents; what exists is not encouraging. However, clinicians have reported anecdotal evidence for using aripiprazole as an augmenting agent. Also, irreversible MAOIs have some positive, although experiential, reports.

Relation to Plastic Surgery. Few data exist about the number of patients seeking plastic surgery who have BDD. One study found that only 2 percent of the patients in a plastic surgery clinic had the diagnosis, but DSM-5 reports the figure to be 7 to 8 percent. The overall percentage may be much higher, however. Surgical requests are varied: removal of facial sags, jowls, wrinkles, or puffiness; rhinoplasty; breast reduction or enhancement; and penile enlargement. Men who request penile enlargements and women who request cosmetic surgery of the labia of the vagina or the lips of the mouth may be suffering from this disorder. Commonly associated with the belief about appearance is an unrealistic expectation of how much surgery will correct the defect. As reality sets in, the person realizes they have not solved their problems by merely altering a perceived cosmetic defect. These patients, hopefully, will explore their feelings of inadequacy using psychotherapy. The patients may take out their unfulfilled expectations and anger by taking legal action against their plastic surgeons or becoming depressed.

Hoarding Disorder

HD is challenging to treat. Although it shows similarities to OCD, effective treatments for OCD have shown little benefit for patients with HD. In one study, only 18 percent of patients responded to medication and CBT. The challenges posed by hoarding patients to typical CBT treatment include poor insight into the behavior and low motivation and resistance to treatment.

The most effective treatment for the disorder is a cognitive-behavioral

model that includes training in decision making and categorizing; exposure and habituation to discarding; and cognitive restructuring. Treatment includes both office and in-home sessions. The role of the therapist in this model is to assist in the development of decision-making skills, to provide feedback about normal saving behavior, and to identify and challenge the patient's erroneous beliefs about possessions. The goal in treatment is to get rid of a significant amount of possessions and make the living space livable. Also, treatment can provide the patients with the skills to maintain a positive balance between the number of possessions and livable space.

Evidence for pharmacologic treatment relies on limited and uncontrolled data that support the use of SSRIs or venlafaxine.

Hair-Pulling Disorder

Early data indicated that hair-pulling disorder, like OCD and BDD, responded more robustly to clomipramine than to desipramine. Unfortunately, subsequent trials of SSRIs and venlafaxine in hair-pulling disorder have not consistently demonstrated efficacy. The most significant positive clinical trial to date is with NAC (1200 to 2400 mg/day), a nutraceutical that acts on the glutamatergic system. However, a trial of NAC in pediatric hair-pulling disorder was negative. There are small controlled trials indicating that dopamine receptor blockers may also be useful in these conditions. Given their favorable side-effect profile, it may be reasonable to use NAC as a first-line agent in adults with hair-pulling disorder, to use SSRIs when patients have comorbid conditions for which these agents are efficacious, and to consider low-dose dopamine receptor blockers in more treatment-refractory cases.

Habit reversal training (HRT) is a set of cognitive-behavioral techniques that have been shown efficacious in the treatment of childhood and adult hair-pulling disorder. Components of HRT include awareness training, competing for response training, and social support. Also, therapists use stimulus control (SC) to change the patient's environment so that hairpulling is more effortful or less reinforcing. Controlled trials of augmentation of HRT/SC with acceptance and commitment therapy, dialectical behavior therapy, or cognitive therapy, have also suggested efficacy in hair-pulling disorder.

Excoriation Disorder

Excoriation disorder is challenging to treat, and there are few data on effective treatments. Most patients do not actively seek treatment due to embarrassment or because they believe their condition is untreatable. There is support for the use of SSRIs. Studies comparing fluoxetine against placebo have shown fluoxetine to be superior in reducing skin-picking.

Other agents have limited data. Lamotrigine has demonstrated inconsistent results. Glutamatergic agents, such as the nutraceutical NAC, have some positive, although anecdotal reports, as do dopamine receptor blockers. Nonpharmacologic treatments include HRT and brief CBT.

EPIDEMIOLOGY

Obsessive-Compulsive Disorder

The rates of OCD are relatively consistent, with a lifetime prevalence in the general population estimated at 2 to 3 percent. Community studies indicate a higher prevalence of OCD in females, but in clinical contexts, there are roughly equal numbers of male and female patients. The mean age of onset is about 19 years, with early-onset more common in males. The onset of the disorder typically occurs in adolescence or childhood, and onset after age 30 is rare.

Body Dysmorphic Disorder

Point prevalence estimates in the United States and elsewhere have ranged from 1.7 to 2.4 percent, indicating that this is one of the more common obsessive-compulsive and related disorders. Furthermore, clinical studies have found high rates of BDD in general adult psychiatric inpatients, in cosmetic surgery clinics, and dermatology clinics.

The mean age of onset is in adolescence. As in the case of OCD, community studies indicate a higher prevalence of females with BDD, while clinical reports indicate a roughly even male:female ratio.

Hoarding Disorder

Most prevalence studies of HD have not used DSM-5 diagnostic criteria.

Available data indicate that HD is remarkably prevalent in Western countries, with one study that employed DSM-5 criteria yielding a point prevalence of 1.5 percent. The male:female ratio is estimated to be about 1. In contrast, in clinics, females are more common than males, perhaps indicating greater insight. Unlike the picture seen in most obsessive-compulsive and related disorders, the prevalence of hoarding increases with age, and in clinical settings, the average age of first treatment is around 50.

Hair-Pulling Disorder

Studies of select populations, such as college students, indicate that the point prevalence of trichotillomania is around 0.5 to 2 percent. Age of onset is typically at menarche, and female:male ratio is about 4:1 in adults. Pediatric samples include an equal distribution between males and females.

Excoriation Disorder

Community-based prevalence studies of excoriation disorder have found a point prevalence of 1.4 to 5.4 percent. Age of onset is somewhat more variable than hair-pulling disorder, although the mean age is 12 years, typically coinciding with the onset of puberty. Although many more females than males have excoriation disorder, the ratio is more even than in the case of hair-pulling disorder.

ETIOLOGY

Obsessive-Compulsive Disorder

OCD is now primarily viewed as a neuropsychiatric disorder that is mediated by specific neurocircuits. From a cognitive-affective neuroscience perspective, OCD has several specific neuropsychological impairments, including cognitive inflexibility and alterations in the habit system. Early clinical work established that OCD could be precipitated by damage to striatal circuitry, as was seen in the global influenza epidemic in the early 20th century. More recent advances have delineated the role of neuroanatomy, neurocircuitry, neurotransmitters, and other molecules involved in the pathogenesis of OCD.

Cognitive and neuropsychological studies of OCD have found several

alterations, including a range of impairments in executive function, and with evidence for cognitive inflexibility, motor impulsivity, and excessive habit formation. Such work is consistent with the hypothesis that OCD represents impaired control of automated, habitual behaviors.

Several brain regions, including the anterior cingulate, orbitofrontal cortex, and striatum, have consistently been implicated in OCD. There is, however, evidence that many other regions have an important role (Fig. 9-4). One hypothesis has been that cortico–striatal–thalamic–cortical (CSTC) circuitry plays a particularly important role in mediating the cognitive-affective impairments seen in OCD, with activation or inhibition of different components of this circuitry driving the compulsive and impulsive features of obsessive-compulsive and related disorders. Early imaging work was seminal in showing that both pharmacotherapy and CBT were able to normalize functional alterations in CSTC circuitry in OCD.

Also, data indicate that a range of neurotransmitter systems contribute to OCD, including serotonergic, dopaminergic, glutamatergic, and GABAergic systems. A serotonin hypothesis of OCD has been influential; a range of evidence points to the involvement of this system in OCD, and patients respond to treatment with SRIs but not to treatment with noradrenergic reuptake inhibitors. At the same time, there is relatively little evidence that serotonin plays a causal role in OCD. Furthermore, a range of evidence points to the involvement of the dopaminergic system in OCD, and, notably, augmentation of serotonin reuptake blockers with dopamine receptor blockers as a first-line intervention for treatment-refractory OCD. Most recently, there has been some interest in other systems, including the glutamatergic system, with evidence that some glutamatergic agents may be useful in this condition.

Genetic findings may increasingly influence future work on the cognitive-affective neuroscience of OCD. Twin and family studies indicate that genetic susceptibility plays a role in OCD, and more so in childhood-onset OCD.

Body Dysmorphic Disorder

There is some evidence that specific cognitive-affective impairments characterize BDD. For example, neuropsychological studies have suggested deficits in executive functioning and visual processing. Brain imaging and

neurogenetic studies have provided some insights into the potential mechanisms that underlie such deficits, and into potential overlaps with other obsessive-compulsive and related disorders. For example, CSTC circuits may be involved, as well as circuits involved in visual processing. Family and twin data provide preliminary evidence for genetic susceptibility, as well as a relationship to OCD. However, the etiology of BDD is still far from clear.

Hoarding Disorder

Patients with HD may demonstrate impairment in various neuropsychological domains, including spatial planning, working memory, response inhibition, and set-shifting. Structural and functional brain imaging studies have indicated that the relevant neurocircuitry overlaps only partially with that involved in OCD. Research on patients with neurologic disorders has suggested that ventromedial prefrontal/anterior cingulate cortices and medial temporal regions are involved in hoarding. Also, animal studies have pointed to a possible role for the dopaminergic system in hoarding, and twin studies indicate genetic susceptibility for developing pathologic hoarding.

Hair-Pulling Disorder

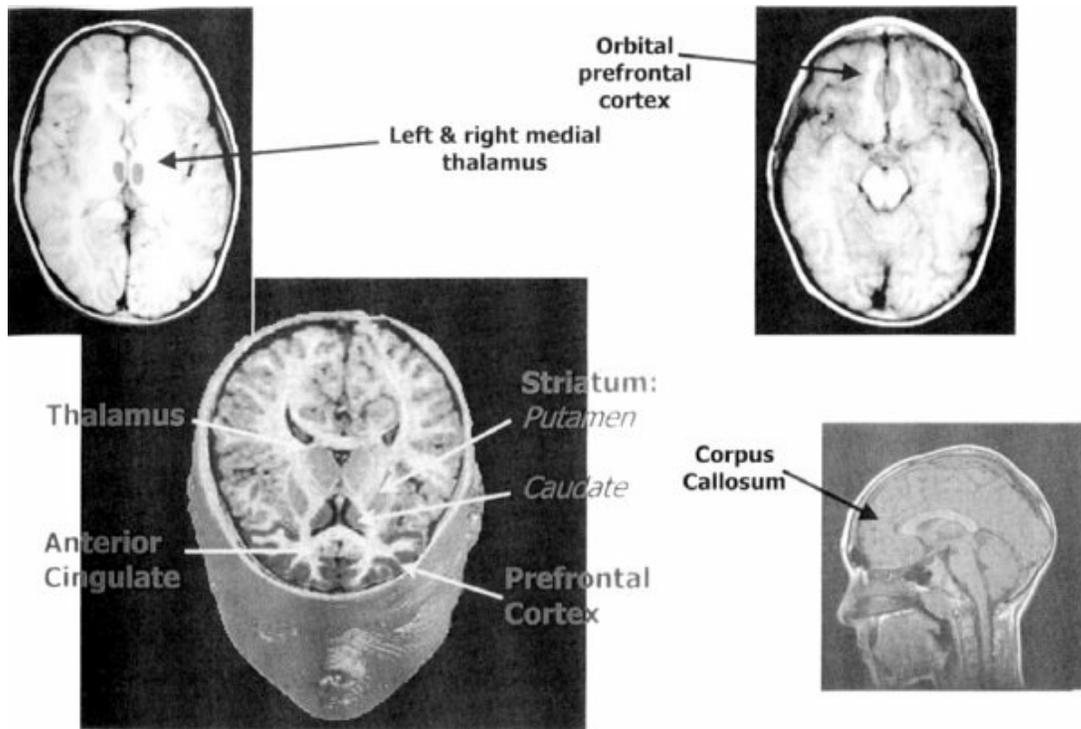
From a cognitive-affective neuroscience perspective, neuropsychological investigations of hair-pulling disorder have demonstrated some evidence of deficits in working memory and visual–spatial learning. Structural and functional brain imaging studies have suggested some involvement of CSTC circuits relevant to habit learning, although data is sparse. There is also evidence of the involvement of brain regions associated with reward processing and affect regulation. Family and twin studies provide evidence for genetic susceptibility, as well as a relationship to OCD and other body-focused repetitive behaviors. Several candidate genes may be associated with hair-pulling disorder, but the evidence is preliminary.


FIGURE 9-4
Brain regions implicated in the pathophysiology of obsessive-compulsive disorder. (From Rosenberg DR, MacMillan SN, Moore GJ. Brain anatomy and chemistry may predict treatment response in paediatric obsessive-compulsive disorder. *Int J Neuropsychopharmacol*. 2001;4(2):179–190, with permission.)

Excoriation Disorder

From a cognitive-affective neuroscience perspective, neuropsychological investigations of excoriation disorder have demonstrated some overlap with OCD regarding motor impulsivity. Brain imaging studies have similarly suggested some involvement of CSTC circuitry, although the data is sparse, and other regions also appear to be implicated. There is also some evidence that suggests that the dopaminergic system plays a role in excoriation disorder. Family and twin studies provide evidence for genetic susceptibility, as well as a relationship to OCD and other body-focused repetitive behaviors. As with hair-pulling disorder, preliminary evidence has identified several candidate genes.

Trauma- and Stressor-Related Disorders

This chapter includes disorders characterized by exposure to significant stress or trauma. These disorders include posttraumatic stress disorder (PTSD), acute stress disorder, and adjustment disorders.

THE CLINICAL PRESENTATION

Persons suffering from one of these disorders develop emotional and behavioral symptoms in response to a significant stressor or traumatic event.

Posttraumatic Stress Disorder and Acute Stress Disorder

Persons who have PTSD or acute stress disorder have increased stress and anxiety following exposure to a traumatic or stressful event. Traumatic or stressful events may include experiencing a violent accident or crime, military combat, assault, being kidnapped, being involved in a natural disaster, being diagnosed with a life-threatening illness, or experiencing systematic physical or sexual abuse. A PTSD patient typically relives the trauma or tries to avoid reminders of it. They experience negative thoughts and moods about the event and feel hyperaroused or hyperactive. The patient may relive the trauma in their dreams or experience "flashbacks" or waking thoughts about the ordeal.

The stressors causing both acute stress disorder and PTSD are sufficiently overwhelming to affect almost everyone. They can arise from experiences in war, torture, natural catastrophes, assault, rape, and serious accidents.

Physicians have appreciated the link between acute mental syndromes and

traumatic events for more than 200 years. After the American Civil War, physicians documented trauma-related syndromes, and early psychoanalytic writers, including Sigmund Freud, noted a relationship between neurosis and trauma. In World Wars I and II, these disorders were given various names, including "battle fatigue," "shell shock," and "soldier's heart." Moreover, increasing documentation of mental reactions to the Holocaust, to a series of natural disasters, and assault contributed to the growing recognition of a close relation between trauma and psychopathology.

Mrs. M sought treatment for symptoms that she developed in the wake of an assault that had occurred about 6 weeks before her psychiatric evaluation. While leaving work late one evening, Mrs. M was attacked in a parking lot next to the hospital in which she worked. She was raped and badly beaten but was able to escape and call for help. On referral, Mrs. M reported frequent intrusive thoughts about the assault, including nightmares about the event and recurrent intrusive visions of her assailant. She now took the bus to work to avoid the scene of the attack and changed her work hours to avoid leaving the building after dark. Also, she reported that she had difficulty interacting with men, particularly those who resembled her attacker, and that she consequently avoided such interactions whenever possible. Mrs. M described increased irritability, difficulty staying asleep at night, poor concentration, and an increased focus on her environment, particularly after dark. (Courtesy of Erin B. McClure-Tone, Ph.D., and Daniel S. Pine, M.D.)

Clinical Features. Individuals with PTSD relive distressing instances of the traumatic event, with vivid emotional proximity and high, imperative intensity. They organize their lives trying to contain and mitigate the persistent effects of the traumatic experience. For those traumatized in a war zone, they often feel as if the war never ended. Victims of rape, assault, or torture describe difficulties engaging and trusting other humans. Constantly reliving the trauma in the present, PTSD patients' lives become a series of effortful attempts to avoid reminders of the traumatic event. They scan the environment for threat signals, which they fearfully expect, and remain on guard, tense, restless, and exhausted. The persistence of symptoms despite

the termination of the threat, combined with an inability to regain a sense of safety, are core features of PTSD. Another core feature is the involuntary, uncontrollable, and intense nature of symptoms.

Adjustment Disorders

People with adjustment disorders have an emotional response to a stressful event. It is one of the few diagnostic entities that directly links an external stressor to the development of symptoms. Typically, the stressor involves financial issues, a medical illness, or a relationship problem. The symptom complex that develops may involve anxious or depressive affect or may present with a disturbance of conduct. The symptoms must begin within 3 months of the stressor. The *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) includes a variety of subtypes of the disorder, including adjustment disorder with depressed mood, mixed anxiety and depressed mood, disturbance of conduct, mixed disturbance of emotions and conduct, and unspecified type.

Clinical Features. Patients with adjustment disorders develop intense emotional or behavioral symptoms in response to one or more external stressors. The intensity of the symptoms is subjectively considered beyond what one would expect in the given situation and impairs the patient's ability to function.

Other Specified or Unspecified Trauma- or Stressor-Related Disorder

As with other psychiatric diagnoses, the DSM-5 includes separate categories to account for persons whose symptoms do not meet the full criteria for another trauma- or stressor-related disorder.

DIAGNOSIS

Posttraumatic Stress Disorder and Acute Stress Disorder

The diagnosis includes several categories of symptoms, including symptoms of intrusion, avoidance, negative mood or cognitions, and hyperarousal. These symptoms cause significant functional impairment and are present for

more than a month.

We outline the diagnostic approach to posttraumatic stress disorder in Table 10-1.

As with most disorders, substance use or a medical condition should not better explain the symptoms.

With acute stress disorder, the primary feature differentiating this disorder from PTSD is the time course, with the symptoms of acute stress disorder occurring 3 days to 1 month following a traumatic event. Acute stress disorder can have any of the symptoms of PTSD; however, they do not have to have all the domains. A person who experiences a minimum of nine symptoms from any of these domains within 3 days to 1 month of a traumatic event meets the criteria for acute stress disorder.

We outline the diagnostic approach to acute stress disorder in Table 10-2.

Three weeks after a train derailment, a 42-year-old budget analyst presented to the mental health clinic. He noted that he was embarrassed to seek care, as he was previously a firefighter, but felt he needed "some reassurance that what I'm experiencing is normal." He reported that, since the wreck, he had been feeling nervous and on edge. He experienced some difficulty focusing his attention at work, and he had occasional intrusive recollections of "the way the ground just shook; the tremendous 'bang' and then the screaming when the train rolled over." He noted that he had spoken with five business colleagues who were also on the train, and three acknowledged similar symptoms. However, they said that they were improving. He was more concerned about the frequency of tearful episodes, sometimes brought on by hearing the name of a severely injured friend, but, at other times, occurring "for no particular reason." Also, he noted that, when he evacuated the train, rescue workers gave him explicit directions about where to report, and, although the man complied, he now felt extremely guilty about not returning to the train to assist in the rescue of others. He reported a modest decrease in appetite and denied weight loss but noted that he had stopped jogging during his lunch break. He had difficulty initiating sleep, so he had begun consuming a "glass or two" of wine before bed to help with this. He did not feel rested on awakening. He denied suicidal

ideation or any psychotic symptoms. His sister had taken an antidepressant several years ago, but he did not desire medication. He feared that side effects could further diminish his ability to function at the workplace and could cause him to gain weight. (Courtesy of D. M. Benedek, M.D., R. J. Ursano, M.D., and H. C. Holloway, M.D.)

Adjustment Disorders

Clinicians tend to use the diagnostic category of adjustment disorders liberally. Although this disorder must follow a stressor, the symptoms do not necessarily begin immediately. Up to 3 months may elapse between a stressor and the development of symptoms. Symptoms do not always subside as soon as the stressor ceases; if the stressor continues, the disorder may be chronic. The disorder can occur at any age, and its symptoms vary considerably, with depressive, anxious, and mixed features most common in adults. Physical symptoms, which are most common in children and the elderly, can occur in any age group. Manifestations may also include impulsivity, violence, excessive alcohol consumption, and suspiciousness.

The clinical presentations of adjustment disorder can vary widely.

We outline the diagnostic approach to adjustment disorder in Table 10-3.

Adjustment Disorder with Depressed Mood. In adjustment disorder with depressed mood, symptoms may manifest as depression, hyposomnia, low self-esteem, or suicidal ideation. We should distinguish this disorder from a major depressive disorder and uncomplicated bereavement.

Adjustment Disorder with Anxiety. Symptoms such as generalized anxiety, increased motor activity, and situational anxiety are present in adjustment disorder with anxiety, which we should differentiate from anxiety disorders.

Adjustment Disorder with Mixed Anxiety and Depressed Mood. In adjustment disorder with mixed anxiety and depressed mood, patients exhibit features of both anxiety and depression that do not meet the criteria for an already established anxiety disorder or depressive disorder.

A 48-year-old married woman, in good health, with no previous psychiatric difficulties, presented to the emergency room, reporting that she had overdosed on a handful of antihistamines shortly before she arrived. She described her problems as having started 2 months earlier, soon after her husband unexpectedly requested a divorce. She felt betrayed after having devoted much of her 20-year marriage to being a wife, mother, and homemaker. She was sad and tearful at times, and she occasionally had difficulty sleeping. Otherwise, she had no vegetative symptoms and enjoyed time with family and friends. She felt desperate and suicidal after she realized that "he no longer loves me." After crisis intervention in the emergency setting, she responded well to individual psychotherapy for over 3 months. She occasionally required benzodiazepines for anxiety during the period of treatment. By the time of discharge, she had returned to her baseline function. She came to terms with the possibility of life after divorce and was exploring her best options under the circumstances. (Courtesy of Jeffrey W. Katzman, M.D., and C. M. A. Geppert, M.D., Ph.D., M.P.H.)

Adjustment Disorder with Disturbance of Conduct. In adjustment disorder with disturbance of conduct, symptoms include impulsivity, lack of insight, and violent behavior. We should differentiate this category from conduct disorder and antisocial personality disorder.

Table 10-1
Posttraumatic Stress Disorder Diagnoses in DSM-5 and ICD-10

	Posttraumatic Stress Disorder	
Disorder	DSM-5	ICD-10
Diagnostic name	Posttraumatic Stress Disorder	Posttraumatic Stress Dis
Duration	≥1 mo	Symptoms arise in week: months following trau

		event

Symptoms	1. History of exposure to (directly experiencing, repeated exposure witnessing in person, learning of occurrence in close acquaintance) actual threatened death, severe injury, or sexual trauma
	2. Intrusive symptoms
	  • Involuntary intrusive memories
	    • In children <6 yr, may see reenactment of event through play
	  • Recurrent nightmares/dreams of the event
	    • In children <6 yr, frightening dreams without identifiable content may be present
	  • Dissociative responses or reliving of prior experience (i.e., flashbacks)
		1. Symptoms arise as a[n] or prolonged respons[e] single or recurrent str[ess] experience that is life[-] threatening or catastr[ophic] severity
		2. Traumatic event wou[ld] distress in most indivi[duals]
		3. Symptoms may inclu[de]
		  • Flashbacks
		  • Dreams/nightmares
		  • Emotional blunting [and] subjective numbne[ss]
		  • Social withdrawal/detachm[ent]
		  • Anhedonia
		  • Avoidance
		  • Hyperarousal/hyper[vigilance]
		  • Sleep disturbance
		4. May or may not be as[sociated] with co-occurring anx[iety] and/or depression

- In children <6 yr, may see reenactment of event through play
- Psychological distress related to exposure to stimuli that are reminders of prior trauma
- Presence of physiologic response to stimuli that are reminders of prior trauma
3. Pattern of avoidance of stimuli associated with prior experience of trauma
   - Avoidance of memories related to trauma
   - Avoidance of external reminders of trauma
4. Negative mood or cognitions related to trauma
   - Impairment in memories related to event
   - Negative perceptions of self and others
   - Cognitive

distortions related to event
- Excessive guilt, anger or fear
- Diminished interest and social withdrawal
- Subjective detachment from others
- Difficulty experiencing positive feelings in response to previously pleasurable stimuli

5. Altered level of arousal
- Irritability and/or anger
- Risk taking
- Hypervigilance
- Increased startle response
- Difficulties with concentration
- Sleep disturbances

| Required number of symptoms | In addition to history of exposure to trauma, must have
 • at least one symptom of intrusion
 • at least one | Any of the above |

	• symptom of avoidance • at least two symptoms of negative mood/cognition • at least two symptoms of arousal alterations
Psychosocial consequences of symptoms	Marked distress and impairment in functioning
Exclusions	• Exposure through media, electronics, movie, or photo • Related to substance use • Related to another medical condition
Symptom specifiers	**With dissociative symptoms:** • **Depersonalization:** perception of feeling outside one's own body • **Derealization:** perception of surrounding environment being unreal or distorted
Course specifiers	**With delayed expression:** • All diagnostic

	criteria not met until 6 mo or more after initial traumatic event	
Severity specifiers		

Table 10-2
Acute Stress Disorder Diagnoses in DSM-5 and ICD-10

	Acute Stress Disorder	
Disorder	**DSM-5**	**ICD-10**
Diagnostic name	Acute Stress Disorder	Acute Stress Reaction
Duration	3 days to <1 mo following exposure to trauma	Symptoms arise transiently in response to emotional or physical stress and usually resolve within hours or days
Symptoms	1. History of exposure to (directly experiencing, repeated exposure witnessing in person, learning of occurrence in close acquaintance) actual threatened death, severe injury, or sexual trauma 2. Presence of symptoms in the following categories	1. Cognitive "daze" 2. Narrowed attention 3. Difficulties with comprehension 4. Disorientation 5. Autonomic symptoms of panic 6. May be followed by further withdrawal from the situation or possible agitation/excitability

	(same as PTSD categories) • Intrusion • Negative mood/cognition • Dissociation • Avoidance • Arousal	7. May have partial or complete amnesia related to the event
Required number of symptoms	Nine symptoms from among the above five categories	
Psychosocial consequences of symptoms	Marked distress and impairment in functioning	
Exclusions (not result of):	Substance Other medical condition Brief psychotic disorder or other psychiatric illness	

Table 10-3
Adjustment Disorder Diagnoses in DSM-5 and ICD-10

	Adjustment Disorders	
Disorder	DSM-5	ICD-10
Diagnostic name	Adjustment Disorder	Adjustment Disorders
Duration	Occurring within 3 mo of an acute stressor and resolving within 6 mo of resolution of stressor	
Symptoms	1. Emotional or	1. Subjective

	behavioral changes 2. Marked distress/impairment that is felt to be out of proportion to the stressor itself	distress/emotional disturbance 2. Arises during period of adaptation to a change or stress 3. Symptoms of depressed mood or anxiety may arise, and conduct disturbance may be noted in adolescents
Required number of symptoms	All of the above	
Psychosocial consequences of symptoms	Marked distress/functional impairment	Often result in impairment in social functioning
Exclusions (not result of):	Exacerbation of existing mental illness Normal bereavement Other psychiatric illness	
Symptom specifiers	**With depressed mood:** • Predominant low mood, hopelessness **With anxiety:** • Predominant anxiety, worry **With mixed anxiety and depressed mood:**	

Adjustment Disorder with Mixed Disturbance of Emotions and Conduct. A combination of disturbances of emotions and conduct sometimes occurs. Examples include excessive alcohol ingestion, suspiciousness, hostility, defrauding behavior, and homicidal ideation. Clinicians are encouraged to try to make one or the other diagnosis in the interest of clarity.

Adjustment Disorder Unspecified. Adjustment disorder unspecified is a residual category for atypical maladaptive reactions to stress. Examples include inappropriate responses to the diagnosis of physical illness, such as massive denial, severe noncompliance with treatment, and social withdrawal, without significant depressed or anxious mood.

Other Specified or Unspecified Trauma- or Stressor-Related Disorder

DSM-5 uses the categories of "other specified trauma- or stressor-related disorder" or "unspecified trauma- or stressor-related disorder" uses for patients who develop emotional or behavioral symptoms in response to an identifiable stressor, but do not meet the full criteria for any of the above disorders. The primary difference between these two categories is that "other specified trauma- or stressor-related disorder" is used when it is essential to convey the reason that the patient does not meet the full criteria for one of the

other disorders.

DIFFERENTIAL DIAGNOSIS FOR THE TRAUMA- AND STRESSOR-RELATED DISORDERS

Generally, the time requirements and diagnostic criteria help to differentiate PTSD, acute stress disorder, and other psychiatric disorders. With adjustment disorder, one of the challenges is that there are no clear criteria that define the stressors that are required to make this diagnosis. PTSD and acute stress disorder have the nature of the stressor better characterized and include a defined constellation of affective, cognitive, and autonomic symptoms. In contrast, the stressor in adjustment disorder can be of any severity, with a wide range of possible symptoms. When the response to an extreme stressor does not meet the acute stress or posttraumatic disorder threshold, the adjustment disorder diagnosis would be appropriate.

We list some common disorders that can also cause posttraumatic symptomatology in Table 10-4.

Posttraumatic Stress Disorder and Acute Stress Disorder

Because patients often exhibit complex reactions to trauma, the clinician must be careful to exclude other syndromes as well when evaluating patients presenting in the wake of trauma. It is particularly important to recognize potentially treatable medical contributors to posttraumatic symptomatology, especially head injury during the trauma. A careful history and examination can help detect medical contributors. Epilepsy, alcohol use disorders, and other substance-related disorders can also either cause or exacerbate the symptoms. Acute intoxication or withdrawal from some substances may also present a clinical picture that is difficult to distinguish from the disorder until the effects of the substance have worn off.

Table 10-4
Differential Diagnosis of Posttraumatic Stress Disorder

Medical causes	Traumatic brain injury
	Epilepsy
	Alcohol use disorder

	Substance-related disorders
	Acute substance or alcohol withdrawal
Psychiatric diagnoses	Panic disorder
	Generalized anxiety disorder
	Major depressive disorder
	Dissociative identity disorder
	Borderline personality disorder
	Factitious disorders
	Acute stress disorder

Symptoms of PTSD can be difficult to distinguish from both panic disorder and generalized anxiety disorder because all three syndromes are associated with prominent anxiety and autonomic arousal. Keys to correctly diagnosing PTSD include a careful review of the time course relating the symptoms to a traumatic event. PTSD is also associated with intrusion symptoms and avoidance of anything that reminds the person of the trauma, something not usually present in panic or generalized anxiety disorder. Major depression is also a frequent concomitant of PTSD. Although the two syndromes are not generally difficult to distinguish phenomenologically, it is essential to note the presence of comorbid depression because this can influence the treatment of PTSD. We also must differentiate PTSD from several related disorders that can look similar, including borderline personality disorder, dissociative disorders, and factitious disorders. Borderline personality disorder can be difficult to distinguish from PTSD. The two disorders can coexist or even be causally related. Patients with dissociative disorders do not usually have the same degree of avoidance and arousal that PTSD patients do. The time course can distinguish PTSD and acute stress disorder.

Adjustment Disorders

Although uncomplicated bereavement often produces temporarily impaired social and occupational functioning, the person's dysfunction remains within the expectable bounds of a reaction to the loss of a loved one and, thus, is not considered adjustment disorder. We discuss uncomplicated bereavement among the depressive disorders in Chapter 7.

We must differentiate adjustment disorder from many other disorders, and we list some of these in Table 10-5. Patients with an adjustment disorder are impaired in social or occupational functioning and show symptoms beyond the usual and expectable reaction to the stressor. Because no absolute criteria help to distinguish an adjustment disorder from another condition, clinical judgment is necessary. Some patients may meet the criteria for both an adjustment disorder and a personality disorder. If the adjustment disorder follows a physical illness, the clinician must make sure that the symptoms are not a continuation or another manifestation of the illness or its treatment.

COMORBIDITY

Posttraumatic Stress Disorder

Comorbidity rates are high among patients with PTSD, with about two-thirds having at least two other disorders. Common comorbid conditions include depressive disorders, substance-related disorders, anxiety disorders, and bipolar disorders. Comorbid disorders make persons more vulnerable to develop PTSD.

Table 10-5
Differential Diagnosis of Adjustment Disorders

Major depressive disorder
Brief psychotic disorder
Generalized anxiety disorder
Somatic symptom disorder
Substance-related disorder
Conduct disorder
Antisocial personality disorder
Posttraumatic stress disorder

Adjustment Disorders

Most psychiatric disorders can co-occur with adjustment disorder. However, it is critical to ensure that another psychiatric disorder does not best explain

the person's response to the stressor.

COURSE AND PROGNOSIS

Posttraumatic Stress Disorder

Immediately following exposure to a traumatic event, many people experience symptoms such as shock, nightmares, and intrusive thoughts about the event. However, we cannot make a diagnosis of PTSD unless enough symptoms persist for at least 1 month. Symptoms can fluctuate over time and may be most intense during periods of stress. Untreated, about 30 percent of patients recover completely, 40 percent continue to have mild symptoms, 20 percent continue to have moderate symptoms, and 10 percent remain unchanged or become worse. After 1 year, about 50 percent of patients will recover.

We list some predictors of good prognosis in Table 10-6.

In general, the very young and the very old have more difficulty with traumatic events than do those in midlife. For example, about 80 percent of young children who sustain a burn injury show symptoms of PTSD 1 or 2 years after the initial injury; only 30 percent of adults who suffer such an injury have symptoms of PTSD after 1 year. Presumably, young children do not yet have adequate coping mechanisms to deal with the physical and emotional insults of the trauma. Likewise, older persons are likely to have more rigid coping mechanisms than younger adults and to be less able to muster a flexible approach to dealing with the effects of trauma. Furthermore, physical disabilities typical of late life can exacerbate the symptoms. Examples include impairments of the nervous system and the cardiovascular system, such as reduced cerebral blood flow, failing vision, palpitations, and arrhythmias. Pre-existing psychiatric disability also increases the effects of stressors. PTSD that is comorbid with other disorders is often more severe and perhaps more chronic and may be challenging to treat. The availability of social supports may also influence the development, severity, and duration of PTSD. In general, patients who have a good network of social support are less likely to have the disorder and to experience it in its severe forms and are more likely to recover faster.

Adjustment Disorders

With appropriate treatment, the overall prognosis of an adjustment disorder is generally favorable. Most patients return to their previous level of functioning within 3 months. Some persons (particularly adolescents) who receive a diagnosis of an adjustment disorder later have mood disorders or substance-related disorders. Adolescents usually require a longer time to recover than adults.

Table 10-6
Positive Prognostic Factors for PTSD

Rapid onset of the symptoms

Short duration of the symptoms (less than 6 mo)

Good premorbid functioning

Strong social supports

Absence of other psychiatric, medical, or substance-related disorders
    or other risk factors

Research has disclosed a risk for suicide not previously fully appreciated. Some studies suggest that a high proportion of patients with adjustment disorders have had past suicide attempts and recent suicidality. This data is difficult to interpret, given the extensive and sometimes inconsistent use of this diagnosis; however, it is critical to evaluate for suicidality in patients with this disorder.

A 16-year-old high school senior's first relationship ended when his girlfriend rejected him. In the weeks after the end of the relationship, he began to exhibit dysphoric mood accompanied by anxiety and psychomotor agitation. He had received counseling in junior high school when his parents divorced, and he began using alcohol and marijuana. His school suspended him during his freshman year for fighting. A month after the breakup, he began to tell his parents that life was no longer worth living without his former girlfriend. Two months later, his parents came home from work and found him hanging in the garage with a note

stating he could not go on alone. (Courtesy of J. W. Katzman, M.D., and C. M. A. Geppert, M.D., Ph.D., M.P.H.)

TREATMENT APPROACH

Posttraumatic Stress Disorder

We list some of the most common treatments for PTSD and related disorders in Table 10-7.

Pharmacotherapy. Currently, selective serotonin reuptake inhibitors (SSRIs), particularly sertraline and paroxetine, have the most robust evidence for efficacy. There are promising initial findings for the noradrenergic and serotonergic reuptake inhibitor venlafaxine, the atypical antipsychotic risperidone, and the anticonvulsant topiramate. We lack evidence for the effectiveness of benzodiazepines, despite their continued use in practice; one meta-analysis went so far as to consider benzodiazepines relatively contraindicated in this population. Finally, the alpha 1-adrenergic antagonist prazosin and the atypical antipsychotics show some efficacy in treatment-resistant PTSD, and prazosin shows effectiveness for treating nightmares. Insomnia is prevalent and disabling in chronic PTSD, with low-dose trazodone preferable to benzodiazepines. The orexin antagonist suvorexant is promising for managing trauma-related insomnia.

**Table 10-7
Treatments for PTSD**

Pharmacologic interventions	Strong evidence
	SSRIs (sertraline, paroxetine)
	Promising initial evidence
	SNRI (venlafaxine)
	Atypical antipsychotic (risperidone)
	Anticonvulsant (topiramate)
	Limited evidence
	Alpha 1-adrenergic antagonist (prazosin)

	<u>Lack of evidence</u>
	Benzodiazepines
	<u>Symptom-specific</u>
	Prazosin (nightmares)
	Orexin (insomnia)
	Trazodone (insomnia)
Psychotherapeutic interventions	Trauma-focused cognitive-behavioral therapy (TFCBT),
	Prolonged exposure (PE) therapy
	Cognitive processing therapy (CPT)
	Eye movement desensitization and reprocessing therapy (EMDR)
	Present centered therapy (PCT)
	Cognitive processing therapy (CPT)
	Psychodynamic psychotherapy
	Group and family therapy

Psychotherapy. Several therapies are effective for PTSD and related disorders; we list these in Table 10-7. Trauma-focused cognitive-behavioral therapy (TFCBT) includes prolonged exposure (PE) therapy, which focuses on reexperiencing the traumatic event through repeatedly engaging with the memories (imaginal exposure) and everyday reminders (in vivo exposure) rather than avoiding triggers. Eye movement desensitization and reprocessing therapy (EMDR) involves repeatedly recalling distressing images while receiving sensory inputs. Present centered therapy (PCT) focuses on the current relationship and work challenges rather than the trauma, and cognitive processing therapy (CPT) emphasizes correcting faulty attributions including posttraumatic overgeneralizations of the world as dangerous, uncontrollable, and unpredictable. Psychodynamic psychotherapy may also be useful in the treatment of many patients with PTSD. In some cases, reconstruction of the traumatic events with associated abreaction and catharsis may be therapeutic. Still, psychotherapy must be tailored to the individual, because reexperiencing the trauma overwhelms some patients.

In addition to individual therapy techniques, group therapy and family

therapy are effective for PTSD. The advantages of group therapy include the sharing of traumatic experiences and support from other group members. Group therapy has been particularly successful with Vietnam veterans and survivors of catastrophic disasters such as earthquakes. Family therapy often helps sustain a marriage through periods of exacerbated symptoms. Hospitalization may be necessary when symptoms are particularly severe or when the risk of suicide or other violence exists.

Adjustment Disorders

Psychotherapy. Psychotherapy remains the treatment of choice for adjustment disorders. Group therapy can be particularly useful for patients who have had similar stresses—for example, a group of retired persons or patients having renal dialysis. Individual psychotherapy interventions include supportive psychological approaches, cognitive-behavioral, problem-solving techniques, and psychodynamic interventions. After successful therapy, patients sometimes emerge from an adjustment disorder stronger than in the premorbid period, although no pathology was evident during that period. Because there is an explicit stressor, some clinicians mistakenly deemphasize psychotherapy and believe that the disorder will remit spontaneously. This viewpoint, however, ignores the fact that many persons exposed to the same stressor experience different symptoms, and in adjustment disorders, the response is pathologic. Psychotherapy can help persons adapt to stressors that are not reversible or time-limited and can serve as a preventive intervention if the stressor does remit.

Crisis Intervention. Crisis intervention and case management are short-term treatments aimed at helping persons with adjustment disorders resolve their situations quickly by supportive techniques, suggestion, reassurance, environmental modification, and even hospitalization, if necessary. The frequency and length of visits for crisis support vary according to patients' needs; daily sessions may be required, sometimes two or three times each day. Flexibility is essential in this approach.

Pharmacotherapy. There is limited evidence for the efficacy of pharmacologic interventions in persons with adjustment disorder. Still, it may

be reasonable to use medication to treat specific symptoms for a brief time. The judicious use of medications can help patients with adjustment disorders, but we should only use them for short periods. Depending on the type of adjustment disorder, a patient may respond to an antianxiety agent or an antidepressant. It is often helpful and important to treat insomnia and severe anxiety with pharmacologic interventions in the short run. It is not as clear whether it helps to treat the depressive symptoms using medication. Clinicians have found some SSRIs to be useful for treating some subthreshold depressive symptoms and may benefit certain subtypes of adjustment disorders. Pharmacologic intervention in this population should mainly augment psychosocial strategies and not serve as the primary modality.

EPIDEMIOLOGY

Posttraumatic Stress Disorder

About 6.8 percent of the general population has a lifetime prevalence of PTSD, with a current past year prevalence estimated at 3.5 percent. The lifetime prevalence rate is 9.7 percent in women and 3.6 percent in men. According to the National Vietnam Veterans Readjustment Study (NVVRS), 30.9 percent of men developed full-blown PTSD after having served in the war, and 26.9 percent of women developed the disorder. A 25-year follow-up of the NVVRS, the National Vietnam Veteran Longitudinal Study (NVVLS), was conducted to assess the course of PTSD 40 years after the war. This study found that the current prevalence of war zone PTSD was 4.5 percent, and the lifetime prevalence of war zone PTSD was 17 percent.

Although PTSD can appear at any age, it is most prevalent in young adults because they tend to be more exposed to precipitating situations. Children can also have the disorder. The disorder is most likely to occur in those who are single, divorced, widowed, socially withdrawn, or of low socioeconomic level, but anyone can be affected, and no one is immune. The most important risk factors, however, for this disorder are the severity, duration, and proximity of a person's exposure to the actual trauma. A familial pattern seems to exist for this disorder, and first-degree biologic relatives of persons with a history of depression have an increased risk for developing PTSD

following a traumatic event.

Adjustment Disorders

Few studies have examined the prevalence of adjustment disorder in community samples. One study that did assess for the presence of adjustment disorder was the European Outcome of Depression International Network (ODIN) study, which found that less than 1 percent of subjects had adjustment disorder. Another study examined the prevalence of adjustment disorder in a primary care setting and found that 2.94 percent of the sample met the criteria for adjustment disorder. There is a higher prevalence of adjustment disorder in the medical setting—especially patients with cancer and those receiving palliative care. For example, one study found that 11 percent of individuals with mixed cancer diagnoses had an adjustment disorder.

ETIOLOGY

Posttraumatic Stress Disorder

Risk Factors for PTSD. Even when faced with overwhelming trauma, most persons do not experience PTSD symptoms. The National Comorbidity Study found that 60 percent of males and 50 percent of females had experienced some significant trauma. In contrast, the reported lifetime prevalence of PTSD, as mentioned earlier, was much lower. Similarly, events that may appear mundane or less than catastrophic to most persons can produce PTSD in some. Evidence indicates a dose–response relationship between the degree of trauma and the likelihood of symptoms.

A meta-analysis of risk factors for PTSD in the community found that female gender, age at trauma, race, lower education, childhood abuse, higher severity of trauma exposure, lack of social support, and additional life stress increased risk for PTSD. A second meta-analysis identified seven predictors: prior trauma, prior psychological adjustment, family history of psychopathology, more significant perceived life threat during the trauma, lower posttrauma social support, more considerable emotional distress during exposure, and higher dissociation during exposure. For combat-related PTSD,

identified risk factors include lower education, nonofficer ranks, army service, combat specialization, higher numbers of deployments, longer cumulative length of deployments, more adverse life events, prior trauma exposure, and previous psychological problems. Various aspects of the trauma period also constituted risk factors, including higher levels of combat exposure, discharging a weapon, witnessing someone being wounded or killed, severe trauma, and deployment-related stressors. Another study reported that killing enemy combatants, prisoners of war, and civilians in the war zone increased the risk of PTSD.

Table 10-8 summarizes vulnerability factors that appear to play etiologic roles in the disorder.

Genetics and Risk for PTSD. Genes account for about 30 percent of the variance in the risk for PTSD. A study of Vietnam veteran twin pairs reported that monozygotic twins of veterans with combat-related PTSD had more significant mood disorder symptoms than monozygotic co-twins of combat controls or dizygotic co-twins of veterans with PTSD. The findings suggest a shared genetic vulnerability to PTSD and mood disorders. Other studies have indicated that PTSD symptoms are moderately heritable, with the remaining vulnerability accounted for by unique environmental experiences. Several common genetic variants are associated with PTSD, including polymorphisms in FKBP5, PACAP1, COMT, DRD2, GABA alpha-2 receptor, G-protein signaling 2 (RSG2), an SNP in an intergenic region of the fourth chromosome, and an estrogen response element on ADCYAP R1. Also, the s/s genotype of the serotonin transporter gene may interact with childhood adversity to increase PTSD risk.

Table 10-8
Predisposing Vulnerability Factors in Posttraumatic Stress Disorder

Presence of childhood trauma

Borderline, paranoid, dependent, or antisocial personality disorder traits

Inadequate family or peer support system

Being female

Genetic vulnerability to psychiatric illness
Recent stressful life changes
Perception of an external locus of control (natural cause) rather than an internal one (human cause)
Recent excessive alcohol intake

Adjustment Disorders

By definition, a stressor precipitates an adjustment disorder. The severity of the stressor or stressors does not always predict the severity of the disorder; the stressor severity is a complex function of degree, quantity, duration, reversibility, environment, and personal context. For example, the loss of a parent is different for a child 10 years of age than for a person 40 years of age. Personality organization and cultural or group norms and values also contribute to the disproportionate responses to stressors.

Stressors may be single, such as the death of a loved one, divorce, losing a job, or medical illness. Alternatively, they can be a combination of any of these. Stressors may be recurrent, such as seasonal business difficulties, or continuous, such as chronic illness or poverty. A discordant intrafamilial relationship can produce an adjustment disorder that affects the entire family system, or the disorder may be limited to a patient who was perhaps the victim of a crime or who has a physical illness. Sometimes, adjustment disorders occur in a group or community setting, and the stressors affect several persons, as in a natural disaster or racial, social, or religious persecution. Specific developmental stages, such as beginning school, leaving home, getting married, becoming a parent, failing to achieve occupational goals, having the last child leave home, and retiring, are often associated with adjustment disorders.

Psychodynamic Factors. Pivotal to understanding adjustment disorders is an understanding of three factors: the nature of the stressor, the conscious and unconscious meanings of the stressor, and the patient's pre-existing vulnerability. A concurrent personality disorder or organic impairment may make a person vulnerable to adjustment disorders. Vulnerability is also associated with the loss of a parent during infancy or growing up in a dysfunctional family. Actual or perceived support from crucial relationships

can affect behavioral and emotional responses to stressors.

Clinicians must undertake a detailed exploration of a patient's experience of the stressor. Some patients commonly place all the blame on a particular event when a less apparent event may have had more significant psychological meaning for the patient. Current events may reawaken past traumas or disappointments from childhood, so patients should be encouraged to think about how the current situation relates to similar past events.

Throughout early development, each child develops a unique set of defense mechanisms to deal with stressful events. Because of higher amounts of trauma or greater constitutional vulnerability, some children have less mature defensive constellations than other children. This disadvantage may cause them as adults to react with substantially impaired functioning when facing a loss, divorce, or a financial setback; those who have developed mature defense mechanisms are less vulnerable and bounce back more quickly from the stressor. Resilience is also crucially determined by the nature of children's early relationships with their parents. Studies of trauma repeatedly indicate that supportive, nurturing relationships prevent traumatic incidents from causing permanent psychological damage.

Psychodynamic clinicians must consider the relationship between a stressor and the human developmental life cycle. When adolescents leave home for college, for example, they are at high developmental risk for reacting with a temporary symptomatic picture. Similarly, if the young person who leaves home is the last child in the family, the parents may be particularly vulnerable to a reaction of adjustment disorder. Moreover, middle-aged persons who are confronting their mortality may be especially sensitive to the effects of loss or death.

Dissociative Disorders

In psychiatry, *dissociation* is an unconscious defense mechanism involving the segregation of any group of mental or behavioral processes from the rest of the person's psychic activity. Dissociative disorders involve this mechanism so that there is a disruption in one or more mental functions, such as memory, identity, perception, consciousness, or motor behavior. The disturbance may be sudden or gradual, transient or chronic, and psychological trauma is often the cause.

DIAGNOSTIC AND CLINICAL FEATURES

Dissociative Amnesia

The main feature of dissociative amnesia is the inability to recall important personal information, usually related to a significant trauma or stressor, that is too extensive to be explained by ordinary forgetfulness. The disorder cannot result from the direct physiologic effects of a substance or a neurologic or other general medical condition.

Table 11-1 lists the different types of dissociative amnesia.

A 45-year-old, divorced, left-handed, male bus dispatcher was seen in psychiatric consultation on a medical unit. He had been admitted with an episode of chest discomfort, light-headedness, and left-arm weakness. He had a history of hypertension and had a medical admission in the past year for ischemic chest pain, although he had not suffered a myocardial infarction. Psychiatric consultation was called, because the patient complained of memory loss for the previous 12 years, behaving and

responding to the environment as if it were 12 years previously (e.g., he did not recognize his 8-year-old son, insisted that he was unmarried, and denied recollection of current events, such as the name of the current president). Physical and laboratory findings were unchanged from the patient's usual baseline. Brain computed tomography (CT) scan was normal.

On mental status examination, the patient displayed intact intellectual function but insisted that the date was 12 years earlier, denying recall of his entire subsequent personal history and of current events for the past 12 years. He was perplexed by the contradiction between his memory and current circumstances. The patient described a family history of brutal beatings and physical discipline. He was a decorated combat veteran, although he described amnestic episodes for some of his combat experiences. In the military, he had been a champion golden glove boxer noted for his powerful left hand.

He was educated about his disorder and given the suggestion that his memory could return as he could tolerate it, perhaps overnight during sleep or perhaps over a longer time. If this strategy was unsuccessful, hypnosis or an amobarbital interview was proposed. (Adapted from a case of Richard J. Loewenstein, M.D., and Frank W. Putnam, M.D.)

Classic Presentation. The classic disorder is an overt, florid, dramatic clinical disturbance that quickly presents for medical attention. A history of extreme acute trauma is typical. It also commonly develops, however, in the context of profound intrapsychic conflict or emotional stress. Patients may present with physical symptoms, alterations in consciousness, depersonalization, derealization, trance states, spontaneous age regression, and even ongoing anterograde dissociative amnesia. There is a significant risk of depression and suicidal ideation. No single personality profile or antecedent history is consistently reported in these patients, although a prior personal or family history of somatoform or dissociative symptoms can predispose individuals to develop acute amnesia during traumatic circumstances. Many of these patients have histories of prior adult or childhood abuse or trauma. In wartime cases, as in other forms of combat-related posttraumatic disorders, the most crucial variable in the development

of dissociative symptoms, however, appears to be the intensity of combat.

Table 11-2 presents the mental status evaluation of dissociative amnesia.

Nonclassic Presentation. These patients frequently come to treatment for a variety of symptoms, such as depression or mood swings, substance abuse, sleep disturbances, somatoform symptoms, anxiety and panic, suicidal or self-mutilating impulses and acts, violent outbursts, eating problems, and interpersonal problems. Self-mutilation and violent behavior in these patients may also occur. Amnesia may also occur for flashbacks or behavioral reexperiencing episodes related to trauma.

Dissociative Fugue. DSM-5 treats dissociative fugue as a subtype of dissociative amnesia, whereas it is a separate diagnosis in ICD-10. It can occur in patients with both dissociative amnesia and dissociative identity disorder.

Dissociative fugue is as sudden, unexpected travel away from home or one's customary place of daily activities. Also, the person cannot recall some or all of one's past. Along with the amnesia, the person is confused about their identity or may even assume a new identity. The disturbance is not due to the direct physiologic effects of a substance or a general medical condition.

Dissociative fugues have been described to last from minutes to months. Some patients report multiple fugues. In some extreme cases of posttraumatic stress disorder (PTSD), a person may awaken from a nightmare in a fugue state. Children or adolescents may be more limited than adults in their ability to travel. Thus, fugues in this population may be brief and involve only short distances.

A teenage girl was continually sexually abused by her alcoholic father and another family friend. She was threatened with perpetration of sexual abuse on her younger siblings if she told anyone about the abuse. The girl became suicidal but felt that she had to stay alive to protect her siblings. She ran away from home after being raped by her father and several of his friends. She traveled to a part of the city where she had lived previously with the idea of finding her grandmother with whom she had lived before the abuse began. She traveled by public transportation and

walked the streets, apparently without attracting attention. After approximately 8 hours, she was stopped by the police in a curfew check. When questioned, she could not recall recent events or give her current address, insisting that she lived with her grandmother. On initial psychiatric examination, she was aware of her identity, but she believed that it was 2 years earlier, giving her age as 2 years younger and insisting that none of the events of recent years had occurred. (Courtesy of Richard J. Loewenstein, M.D., and Frank W. Putnam, M.D.)

Table 11-1
Types of Dissociative Amnesia

Localized amnesia: Inability to recall events related to a circumscribed period of time

Selective amnesia: Ability to remember some, but not all, of the events occurring during a circumscribed period of time

Generalized amnesia: Failure to recall one's entire life

Continuous amnesia: Failure to recall successive events as they occur

Systematized amnesia: Failure to remember a category of information, such as all memories relating to one's family or to a particular person

Table 11-2
Mental Status Examination Questions for Dissociative Amnesia

If answers are positive, ask the patient to describe the event. Make sure to specify that the symptom does not occur during an episode of intoxication.

1. Do you ever have blackouts? Blank spells? Memory lapses?
2. Do you lose time? Have gaps in your experience of time?
3. Have you ever traveled a considerable distance without recollection of how you did this or where you went exactly?

4. Do people tell you of things you have said and done that you do not recall?
5. Do you find objects in your possession (such as clothes, personal items, groceries in your grocery cart, books, tools, equipment, jewelry, vehicles, weapons, and so on) that you do not remember acquiring? Out-of-character items? Items that a child might have? Toys? Stuffed animals?
6. Have you ever been told or found evidence that you have talents and abilities that you did not know that you had? For example, musical, artistic, mechanical, literary, athletic, or other talents? Do your tastes seem to fluctuate a lot? For example, food preference, personal habits, taste in music or clothes, and so forth.
7. Do you have gaps in your memory of your life? Are you missing parts of your memory for your life history? Are you missing memories of some important events in your life? For example, weddings, birthdays, graduations, pregnancies, birth of children, and so on.
8. Do you lose track of or tune out conversations or therapy sessions as they are occurring? Do you find that, while you are listening to someone talk, you did not hear all or part of what was just said?
9. What is the longest period of time that you have lost? Minutes? Hours? Days? Weeks? Months? Years? Describe.

Adapted from Loewenstein RJ. An office mental status examination for chronic complex dissociative symptoms and multiple personality disorder. *Psychiatr Clin North Am*. 1991;14(3):567–604.

After the termination of a fugue, the patient may experience perplexity, confusion, trance-like behaviors, depersonalization, derealization, and conversion symptoms, in addition to amnesia. Some patients may terminate a fugue with an episode of generalized dissociative amnesia.

As the patient with dissociative fugue begins to become less dissociated, he or she may display mood disorder symptoms, intense suicidal ideation, and PTSD or anxiety disorder symptoms. In classic cases, the person has an alter identity under whose auspices the patient lives for a period. Many of these latter cases are better classified as dissociative identity disorder or, if

using DSM-5, as other specified dissociative disorder with features of dissociative identity disorder.

Differential Diagnosis

Table 11-3 lists the differential diagnosis of dissociative amnesia.

Ordinary Forgetfulness and Nonpathologic Amnesia. Ordinary forgetfulness is benign and unrelated to stressful events. In dissociative amnesia, memory loss is more extensive than in nonpathologic amnesia. There are other types of nonpathologic amnesia as well, including infantile and childhood amnesia, amnesia for sleep and dreaming, and hypnotic amnesia.

Dementia, Delirium, and Amnestic Disorders due to Medical Conditions. In patients with dementia, delirium, and amnestic disorders due to medical conditions, memory loss is part of a more extensive set of cognitive, language, attentional, behavioral, and memory problems. Loss of memory for personal identity is usually not found without evidence of a marked disturbance in many domains of cognitive function. Causes of organic amnestic disorders include Korsakoff psychosis, cerebral vascular accident (CVA), postoperative amnesia, postinfectious amnesia, anoxic amnesia, and transient global amnesia (see below). Electroconvulsive therapy (ECT) may also cause marked temporary amnesia, as well as persistent memory problems in some cases. Here, however, memory loss for autobiographical experience is unrelated to traumatic or overwhelming experiences and seems to involve many different types of personal experiences, most commonly those occurring just before or during the ECT treatments.

Posttraumatic Amnesia. In posttraumatic amnesia caused by brain injury, we usually find a history of a clear-cut physical trauma, a period of unconsciousness or amnesia, or both. Also, there is objective clinical evidence of brain injury.

Seizure Disorders. In most seizure cases, the clinical presentation differs significantly from that of dissociative amnesia, with clear-cut ictal events and

sequelae. In complex–partial seizures, patients may wander or show semipurposeful behavior, or both, during seizures or in postictal states, for which subsequent amnesia occurs. Rarely, patients with recurrent, complex–partial seizures present with ongoing bizarre behavior, memory problems, irritability, or violence, leading to a differential diagnostic puzzle. Seizure patients in an epileptic fugue often exhibit abnormal behavior, however, including confusion, perseveration, and abnormal or repetitive movements. Patients with pseudoepileptic seizures may also have dissociative symptoms, such as amnesia and an antecedent history of psychological trauma. In some of these cases, the diagnosis can be clarified only by telemetry or ambulatory electroencephalographic (EEG) monitoring.

Table 11-3
Differential Diagnosis of Dissociative Amnesia

Ordinary forgetfulness	Acute stress disorder
Age-related cognitive decline	Posttraumatic stress disorder
Nonpathologic forms of amnesia	Somatization disorder
	Psychotic episode
Infantile and childhood amnesia	Lack of memory for psychotic episode when returns to nonpsychotic state
Amnesia for sleep and dreaming	Mood disorder episode
Hypnotic amnesia	Lack of memory for aspects of episode of mania when depressed and vice versa or when euthymic
Dementia	Factitious disorder
Delirium	Malingering
Amnestic disorders	Psychophysiologic symptoms or disorders
Neurologic disorders with discrete memory loss episodes	Asthma and breathing problems
	Perimenstrual disorders
	Irritable bowel syndrome
Posttraumatic amnesia	Gastroesophageal reflux disease
	Somatic memory
Transient global	Affective symptoms
	Depressed mood, dysphoria, or

amnesia	anhedonia
Amnesia related to seizure disorders	Brief mood swings or mood lability
Substance-related amnesia	Suicidal thoughts and attempts or self-mutilation
Alcohol	Guilt and survivor guilt
Sedative–hypnotics	Helpless and hopeless feelings
Anticholinergic agents	Obsessive-compulsive symptoms
Steroids	Ruminations about trauma
Marijuana	Obsessive counting, singing
Narcotic analgesics	Arranging
Psychedelics	Washing
Phencyclidine	Checking
Methyldopa (Aldomet)	
Pentazocine (Talwin)	
Hypoglycemic agents	
β-Blockers	
Lithium carbonate	
Many others	
Other dissociative disorders	
Dissociative fugue	
Dissociative identity disorder	
Dissociative disorder not otherwise specified	

Substance-Related Amnesia. A variety of substances and intoxicants can cause amnesia. Table 11-3 lists some common offending agents.

Transient Global Amnesia. Transient global amnesia can be mistaken for dissociative amnesia, especially because stressful life events may precede either disorder. In transient global amnesia, however, there is the sudden onset of complete anterograde amnesia and learning abilities; pronounced

retrograde amnesia; preservation of memory for personal identity; anxious awareness of memory loss with repeated, often perseverative, questioning; overall normal behavior; lack of gross neurologic abnormalities in most cases; and rapid return of baseline cognitive function, with a persistent short retrograde amnesia. The patient usually is older than 50 years of age and shows risk factors for cerebrovascular disease, although epilepsy and migraine are also possible causes.

Dissociative Identity Disorder. Patients with dissociative identity disorder can present with acute forms of amnesia and fugue episodes. These patients, however, have symptoms beyond that found in dissociative amnesia. Concerning amnesia, most patients with dissociative identity disorder, and those with an unspecified dissociative disorder with dissociative identity disorder features, report multiple forms of complex amnesia, including recurrent blackouts, fugues, unexplained possessions, and fluctuations in skills, habits, and knowledge.

Acute Stress Disorder and Posttraumatic Stress Disorder. Many trauma spectrum disorders, including acute stress disorder and PTSD, are associated with dissociative amnesia. When diagnoses of acute stress disorder or PTSD are appropriate, we should add the co-occurring diagnosis of dissociative amnesia if the amnesia persists beyond the immediate trauma.

Malingering and Factitious Amnesia. No absolute way exists to differentiate dissociative amnesia from factitious or malingered amnesia. Malingerers may continue their deception even during hypnotically or barbiturate-facilitated interviews. A patient who presents to psychiatric attention seeking to recover repressed memories as a chief complaint most likely has a factitious disorder or has been subject to suggestive influences. Most of these individuals do not describe bona fide amnesia when carefully questioned but are often insistent that they must have been abused in childhood to explain their unhappiness or dysfunction. Malingering of dissociative fugue can occur in individuals who are attempting to flee a situation involving legal, financial, or personal difficulties, as well as in soldiers who are attempting to avoid combat or unpleasant military duties. No test, battery of tests, or set of procedures exist that invariably distinguish

actual dissociative symptoms from malingering. Many malingerers confess spontaneously or when confronted. In the forensic context, when a patient claims to have a fugue, the examiner should always carefully consider the diagnosis of malingering.

DEPERSONALIZATION/DEREALIZATION DISORDER

Depersonalization is the persistent or recurrent feeling of detachment or estrangement from one's self. The individual may report feeling like an automaton or watching himself or herself in a movie. Derealization is somewhat related and refers to feelings of unreality or of being detached from one's environment. The patient may describe his or her perception of the outside world as lacking lucidity and emotional coloring, as though dreaming or dead.

Table 11-4

Psychosocial impact	Marked distress and/or impairment	

Table 11-4 compares the diagnostic approaches to depersonalization/derealization disorder.

Several distinct components comprise the experience of depersonalization, including a sense of (1) bodily changes, (2) duality of self as observer and actor, (3) feeling cut off from others, and (4) feeling cut off from one's own emotions. Patients experiencing depersonalization often have great difficulty expressing what they are feeling. Trying to express their subjective suffering with banal phrases, such as "I feel dead," "Nothing seems real," or "I'm standing outside of myself," depersonalized patients may not adequately convey to the examiner the distress they experience. While complaining bitterly about how this is ruining their life, they may nonetheless appear remarkably without distress.

Ms. R was a 27-year-old, unmarried, graduate student with a master's degree in biology. She complained about intermittent episodes of "standing back," usually associated with anxiety-provoking social situations. When asked about a recent episode, she described presenting in a seminar course. "All of a sudden, I was talking, but it didn't feel like it was me talking. It was very disconcerting. I had this feeling, 'Who's doing the talking?' I felt like I was just watching someone else talk. Listening to words come out of my mouth, but I wasn't saying them. It wasn't me. It went on for a while. I was calm, even sort of peaceful. It was as if I was very far away. In the back of the room somewhere—just watching myself. But the person talking didn't even seem like me really. It was like I was watching someone else." The feeling lasted the rest of that day and persisted into the next, during which time it gradually

dissipated. She thought that she remembered having similar experiences during high school but was confident that they occurred at least once a year during college and graduate school.

As a child, Ms. R reported frequent intense anxiety from overhearing or witnessing the frequent violent arguments and periodic physical fights between her parents. In addition, the family was subject to many unpredictable dislocations and moves owing to the patient's father's intermittent difficulties with finances and employment. The patient's anxieties did not abate when the parents divorced when she was a late adolescent. Her father moved away and had little further contact with her. Her relationship with her mother became increasingly angry, critical, and contentious. She was unsure if she experienced depersonalization during childhood while listening to her parents' fights. (Adapted from a case of Richard J. Loewenstein, M.D., and Frank W. Putnam, M.D.)

Differential Diagnosis

The variety of conditions associated with depersonalization complicates the differential diagnosis of depersonalization disorder. Depersonalization can result from a medical condition or neurologic condition, intoxication or withdrawal from illicit drugs, as a side effect of medications, or can be associated with panic attacks, phobias, PTSD, or acute stress disorder, major depression, schizophrenia, illness anxiety disorder, or another dissociative disorder. A thorough medical and neurologic evaluation is essential, including standard laboratory studies, an EEG, and any indicated drug screens. Drug-related depersonalization is typically transient. However, persistent depersonalization can follow an episode of intoxication with a variety of substances, including marijuana, cocaine, and other psychostimulants. A range of neurologic conditions, including seizure disorders, brain tumors, postconcussion syndrome, metabolic abnormalities, migraine, vertigo, and Ménière disease, have been reported as causes. Depersonalization caused by organic conditions tends to be primarily sensory without the elaborated descriptions and personalized meanings common to psychiatric etiologies.

DISSOCIATIVE IDENTITY DISORDER

Dissociative identity disorder, previously called multiple personality disorder, has been the most extensively researched of all the dissociative disorders. It is the presence of two or more distinct identities or personality states. The identities or personality states, sometimes called *alters, self-states, alter identities,* or *parts,* among other terms, differ from one another in that each presents as having its pattern of perceiving, relating to, and thinking about the environment and self, in short, its personality. It is the paradigmatic dissociative psychopathology in that the symptoms of all the other dissociative disorders occur in patients with dissociative identity disorder: amnesia, often with fugue, depersonalization, derealization, and similar symptoms.

Diagnostic Features

The critical feature in diagnosing this disorder is the presence of two or more distinct personality states. Also, individuals with this disorder often report losing time beyond what one would expect from ordinary forgetfulness. There are many other diverse signs and symptoms, making diagnosis difficult. Table 11-5 describes the many other associated symptoms commonly found in patients with dissociative identity disorder, and Table 11-6 compares the different diagnostic approaches to dissociative identity disorder.

Mental Status

A careful and detailed mental status examination is essential in making the diagnosis. It is easy to mistake patients with this disorder as suffering from schizophrenia, borderline personality disorder, or outright malingering. Table 11-7 lists the questions clinicians should ask to make the proper diagnosis.

Memory and Amnesia Symptoms

Dissociative disturbances of memory are manifest in several fundamental ways and are frequently observable in clinical settings. As part of the general mental status examination, clinicians should routinely inquire about experiences of losing time, blackout spells, and significant gaps in the

continuity of recall for personal information. Dissociative time loss experiences are too extensive to be explained by normal forgetting and typically have sharply demarcated onsets and offsets.

Patients with dissociative identity disorder often report significant gaps in autobiographical memory, especially for childhood events. Dissociative gaps in the autobiographical recall are usually sharply demarcated and do not fit the usual decline in autobiographical recall for younger ages.

Table 11-5

Checking

Ms. A, a 33-year-old married woman employed as a librarian in a school for disturbed children, presented to psychiatric attention after discovering her 5-year-old daughter "playing doctor" with several neighborhood children. Although this event was of little consequence, the patient began to become fearful that her daughter would be molested. The patient was seen by her internist and was treated with antianxiety agents and antidepressants, but with little improvement. She sought psychiatric consultation from several clinicians but repeated, appropriate trials of antidepressants, antianxiety agents, and supportive psychotherapy resulted in limited improvement. After the death of her father from complications of an alcohol use disorder, the patient became more symptomatic. He was estranged from the family since the patient was approximately 12 years of age, owing to his drinking and associated antisocial behavior.

   Psychiatric hospitalization was precipitated by the patient's arrest for disorderly conduct in a nearby city. She was found in a hotel, in revealing clothing, engaged in an altercation with a man. She denied knowledge of how she had come to the hotel, although the man insisted that she had come there under a different name for a voluntary sexual encounter.

   On psychiatric examination, the patient described dense amnesia for the first 12 years of her life, with the feeling that her "life started at 12 years old." She reported that, for as long as she could remember, she had an imaginary companion, an elderly black woman, who advised her and kept her company. She reported hearing other voices in her head: several women and children, as well as her father's voice repeatedly speaking to her in a derogatory way. She reported that since age 12, she had episodes of amnesia: for work, for her marriage, for the birth of her children, and her sex life with her husband. She reported perplexing changes in skills; for example, people told her that she played the piano well but had no conscious awareness that she could do so. Her husband reported that she had always been "forgetful" of conversations and family activities. He

also noted that, at times, she would speak like a child; at times, she would adopt a southern accent; and, at other times, she would be angry and provocative. She frequently had little recall of these episodes.

When questioned about her early life, the patient appeared to enter a trance and stated, "I just don't want to be locked in the closet" in a childlike voice. Inquiry about this produced rapid shifts in a state between alter identities who differed in manifested age, facial expression, voice tone, and knowledge of the patient's history. One spoke in an angry, expletive-filled manner and appeared irritable and preoccupied with sexuality. She discussed the episode with the man in the hotel and stated that it was she who had arranged it. Gradually, the alters described a history of family chaos, brutality, and neglect during the first 12 years of the patient's life, until her mother, who also struggled with alcohol use disorder, achieved sobriety and fled her husband, taking her children with her. The patient, in the alter identities, described episodes of physical abuse, sexual abuse, and emotional torment by the father, her siblings, and her mother.

After an assessment of family members, the patient's mother also met diagnostic criteria for dissociative identity disorder, as did her older sister, who also had been molested. A brother met diagnostic criteria for PTSD, major depression, and alcohol use disorder. (Adapted from a case of Richard J. Loewenstein, M.D., and Frank W. Putnam, M.D.)

Table 11-7
Mental Status Examination Questions for Dissociative Identity Disorder Process Symptoms

If answers are positive, ask the patient to describe the event. Make sure to specify that the symptom does not occur during an episode of intoxication.

1. Do you act so differently in one situation compared to another situation that you feel almost like you were two different people?
2. Do you feel that there is more than one of you? More than one part of you? Side of you? Do they seem to be in conflict or in a struggle?
3. Does that part (those parts) of you have its (their) own independent way(s) of thinking, perceiving, and relating to the world and the self? Have its (their) own memories, thoughts, and feelings?
4. Does more than one of these entities take control of your behavior?
5. Do you ever have thoughts or feelings, or both, that come from inside you (outside you) that you cannot explain? That do not feel like thoughts or feelings that you would have? That seem like thoughts or feelings that are not under your control (passive influence)?
6. Have you ever felt that your body was engaged in behavior that did not seem to be under your control? For example, saying things, going places, buying things, writing things, drawing or creating things, hurting yourself or others, and so forth? That your body does not seem to belong to you?
7. Do you ever feel that you have to struggle against another part of

you that seems to want to do or to say something that you do not wish to do or to say?

8. Do you ever feel that there is a force (pressure, part) inside you that tries to stop you from doing or saying something?

9. Do you ever hear voices, sounds, or conversations in your mind? That seem to be discussing you? Commenting on what you do? Telling you to do or not do certain things? To hurt yourself or others? That seem to be warning you or trying to protect you? That try to comfort, support, or soothe you? That provide important information about things to you? That argue or say things that have nothing to do with you? That have names? Men? Women? Children?

10. I would like to talk with that part (side, aspect, facet) of you (of the mind) that is called the "angry one" (the Little Girl, Janie, that went to Atlantic City last weekend and spent lots of money, etc.). Can that part come forward now, please?

11. Do you frequently have the experience of feeling like you are outside yourself? Inside yourself? Beside yourself, watching yourself as if you were another person?

12. Do you ever feel disconnected from yourself or your body as if you (your body) were not real?

13. Do you frequently experience the world around you as unreal? As if you are in a fog or daze? As if it were painted? Two-dimensional?

14. Do you ever look in the mirror and not recognize who you see? See someone else there?

Adapted from Loewenstein RJ. An office mental status examination for chronic complex dissociative symptoms and multiple personality disorder. *Psychiatr Clin North Am*. 1991;14:567–604, with permission.

Dissociative Alterations in Identity

Clinically, dissociative alterations in identity may first manifest with odd first-person plural or third-person singular or plural self-references. Also, patients may refer to themselves using their first names or make depersonalized self-references, such as "the body," when describing themselves and others. Patients often describe a profound sense of

concretized internal division or personified internal conflicts between parts of themselves. In some instances, these parts may have proper names, or the patient may refer to them by their predominate affect or function, for example, "the angry one" or "the wife." Patients may suddenly change how they refer to others, for example, "the son" instead of "my son."

Other Associated Symptoms

Most patients with dissociative identity disorder meet the criteria for a mood disorder, usually one of the depression spectrum disorders. Frequent, rapid mood swings are common but are usually part of posttraumatic and dissociative phenomena, not a cyclic mood disorder. Considerable overlap may exist between PTSD symptoms of anxiety, disturbed sleep, and dysphoria, and mood disorder symptoms.

Obsessive-compulsive personality traits are common in dissociative identity disorder, and intercurrent obsessive-compulsive disorder (OCD) symptoms occur in patients with dissociative identity disorder, with a subgroup manifesting severe OCD symptoms. OCD symptoms commonly have a posttraumatic quality: repeatedly checking to be sure that no one can enter the house or the bedroom, compulsive washing to relieve a feeling of being dirty because of abuse, and repetitive counting or singing in one's head to distract from anxiety over being abused, for example.

Child and Adolescent Presentations

Children and adolescents manifest the same core dissociative symptoms and secondary clinical phenomena as adults. Age-related differences in autonomy and lifestyle, however, may significantly influence the clinical expression of dissociative symptoms in youth. Younger children have a less linear and less continuous sense of time and often are not able to self-identify dissociative discontinuities in their behavior. Often additional informants, such as teachers and relatives, are available to help document dissociative behaviors.

Several normal childhood phenomena, such as imaginary companionship and elaborated daydreams, must be carefully differentiated from pathologic dissociation in younger children. The clinical presentation may be that of an elaborated or autonomous imaginary companionship, with the imaginary companions taking control of the child's behavior, often experienced through

passive influence experiences or auditory pseudohallucinations, or both, that command the child to behave in specific ways.

Differential Diagnosis

Table 11-8 lists the most common differentials for dissociative identity disorder.

Factitious, Imitative, and Malingered Dissociative Identity Disorder. Indicators of falsified or *imitative dissociative identity disorder* include those typical of other factitious or malingering presentations. These include symptom exaggeration, lies, use of symptoms to excuse antisocial behavior (e.g., amnesia only for bad behavior), amplification of symptoms when under observation, refusal to allow collateral contacts, legal problems, and pseudologia fantastica. Patients with genuine dissociative identity disorder are usually confused, conflicted, ashamed, and distressed by their symptoms and trauma history. Those with the nongenuine disorder frequently show little dysphoria about their disorder.

Deep-trance phenomena

OTHER SPECIFIED OR UNSPECIFIED DISSOCIATIVE DISORDER

The categories of specified or unspecified dissociative disorders cover all the conditions characterized by a primary dissociative response that does not meet diagnostic criteria for one of the other DSM-5 dissociative disorders. Specified dissociative disorders include chronic and recurrent syndromes of mixed dissociative symptoms; identity disturbance due to prolonged and intense coercive persuasion (e.g., brainwashing); acute dissociative reactions to stressful events; and dissociative trance.

Dissociative Trance

Dissociative trance is manifest by a temporary, marked alteration in the state of consciousness or by loss of the customary sense of personal identity without the replacement by an alternate sense of identity. A variant of this, possession trance, involves single or episodic alternations in the state of consciousness, characterized by the exchange of the person's customary identity with a new identity usually attributed to a spirit, divine power, deity, or another person. In this possessed state, the individual exhibits stereotypical and culturally determined behaviors or experiences an entity controlling them. There must be partial or full amnesia for the event. The trance or possession state must not be a commonly accepted part of cultural or religious practice and must cause significant distress or functional impairment in one or more of the usual domains. Finally, the dissociative trance state must not occur exclusively during a psychotic disorder and is not the result of any substance use or general medical condition.

Brainwashing

DSM-5 describes this dissociative disorder as "identity disturbance due to prolonged and intense coercive persuasion." Brainwashing occurs mostly in the setting of political reform, as has been described at length with the Cultural Revolution in communist China, war imprisonment, torture of political dissidents, terrorist hostages, and, more familiarly, in Western culture, totalitarian cult indoctrination. It implies that under conditions of adequate stress and duress, those in power can make individuals comply with

their demands, thereby undergoing significant changes in their personality, beliefs, and behaviors. Persons subjected to such conditions can undergo considerable harm, including loss of health and life, and they typically manifest a variety of posttraumatic and dissociative symptoms.

Some have likened the first stage in coercive processes to the artificial creation of an identity crisis, with the emergence of a new pseudoidentity that manifests characteristics of a dissociative state. Under circumstances of extreme and malignant dependency, overwhelming vulnerability, and danger to one's existence, individuals develop a state characterized by an extreme idealization of their captors, with ensuing identification with the aggressor and externalization of their superego, regressive adaptation known as *traumatic infantilism,* paralysis of will, and a state of frozen fright. The coercive techniques include isolation of the subject, degradation, control of overall communications and essential daily functions, induction of fear and confusion, peer pressure, assignment of repetitive and monotonous routines, the unpredictability of environmental supplies, renunciation of past relationships and values, and various deprivations. Even though physical or sexual abuse, torture, and extreme sensory deprivation and physical neglect can be part of this process, they are not required to define a coercive process. As a result, victims manifest extensive posttraumatic and dissociative symptomatology, including drastic alteration of their identity, values, and beliefs; reduction of cognitive flexibility with regression to simplistic perceptions of good versus evil and dominance versus submission; numbing of experience and blunting of affect; trance-like states and diminished environmental responsiveness; and, in some cases, more severe dissociative symptoms such as amnesia, depersonalization, and shifts in identity.

Ganser Syndrome

Ganser syndrome is a poorly understood condition characterized by the giving of approximate answers (*paralogia*), together with a clouding of consciousness, and, often, hallucinations and other dissociative, somatoform, or conversion symptoms.

The symptom of *passing over* (*vorbeigehen*) the correct answer for a related but incorrect one is the hallmark of Ganser syndrome. The approximate answers often just miss the mark but bear an obvious relation to

the question, indicating that the person must have understood. When asked how old she was, a 25-year-old woman answered, "I'm not five." If asked to do simple calculations (e.g., 2 + 2 = 5); for general information (the capital of the United States is New York); to identify simple objects (a pencil is a key); or to name colors (green is gray), the patient with Ganser syndrome gives erroneous but comprehensible answers. They may even answer incorrectly to rhetorical questions ("how many legs are on a three-legged stool?" "Four?")

A clouding of consciousness also occurs, usually manifest by disorientation, amnesias, loss of personal information, and some impairment of reality testing. Visual and auditory hallucinations occur in roughly one-half of the cases. Neurologic examination may reveal what Ganser called *hysterical stigmata,* for example, nonneurologic analgesia or shifting hyperalgesia. It must include other dissociative symptoms, such as amnesias, conversion symptoms, or trance-like behaviors.

Differential Diagnosis. The examiner should conduct a thorough neurologic and medical evaluation, given the reported frequent history of organic brain syndromes, seizures, head trauma, and psychosis in Ganser syndrome. Differential diagnoses include organic dementia, depressive pseudodementia, the confabulation of Korsakoff syndrome, organic dysphasia, and reactive psychoses. Patients with dissociative identity disorder occasionally may also exhibit Ganser-like symptoms.

COMORBIDITY

Common comorbidities found in dissociative disorders include depressive disorders, adjustment disorder, anxiety disorders, trauma and stress-related disorders, eating disorders, OCD, somatic symptom disorders, and conversion disorder. Individuals with dissociative disorders may also meet the criteria for personality disorders, with reports of co-occurring avoidant, borderline, dependent, and obsessive-compulsive personality disorders predominating.

COURSE AND PROGNOSIS

Dissociative Amnesia

We know little about the clinical course of dissociative amnesia. After removing the person to safety from traumatic or overwhelming circumstances, the acute dissociative amnesia frequently spontaneously resolves. At the other extreme, some patients do develop chronic forms of generalized, continuous, or severe localized amnesia and are profoundly disabled and require high levels of social support, such as nursing home placement or intensive family caretaking. Clinicians should try to restore patients' lost memories to consciousness as soon as possible; otherwise, the repressed memory may form a nucleus in the unconscious mind around which future amnestic episodes may develop.

In those who develop a dissociative fugue, most fugue states are relatively brief, lasting from hours to days. Most individuals appear to recover, although refractory dissociative amnesia may persist in rare cases. Some studies have described recurrent fugues in most individuals presenting with an episode of dissociative fugue.

Depersonalization/Derealization Disorder

Depersonalization after traumatic experiences or intoxication commonly remits spontaneously after removal from the traumatic circumstances or ending of the episode of intoxication. Depersonalization accompanying mood, psychotic, or other anxiety disorders commonly remit with the definitive treatment of these conditions.

Depersonalization disorder may have an episodic, relapsing and remitting, or chronic course. Many patients with chronic depersonalization may have a severe and chronic functional impairment. The mean age of onset is usually late adolescence or early adulthood.

Dissociative Identity Disorder

We know little about the natural history of untreated dissociative identity disorder. Some individuals with untreated dissociative identity disorder may continue in abusive relationships or violent subcultures, or both, that may result in the traumatization of their children, with the potential for additional family transmission of the disorder. Many authorities believe that some percentage of patients with undiagnosed or untreated dissociative identity disorder die by suicide or because of their risk-taking behaviors.

Prognosis is poorer in patients with comorbid medical disorders, psychotic disorders (*not* dissociative identity disorder pseudopsychosis), and severe medical illnesses. Refractory substance use and eating disorders also suggest a poorer prognosis. Other factors that usually indicate a poorer outcome include significant antisocial personality features, current criminal activity, ongoing perpetration of abuse, and current victimization, with the refusal to leave abusive relationships. Repeated adult traumas with recurrent episodes of acute stress disorder may severely complicate the clinical course.

TREATMENT

Dissociative Amnesia

Psychotherapy

PHASE-ORIENTED TREATMENT. Phase-oriented treatment is the current standard of care for the treatment of dissociative amnesia, although there are no systematic studies with large cohorts of dissociative amnesia patients. This phasic treatment follows the three-stage phasic treatment model developed for the treatment of complex PTSD and dissociative identity disorder, which is discussed extensively in the section on treatment of dissociative identity disorder, below. When applied to dissociative amnesia treatment, memory recall is a central issue, because the loss of memory for personal identity and gaps in current autobiographical memory are acutely disabling symptoms that require relatively rapid intervention.

COGNITIVE THERAPY. Cognitive therapy may have specific benefits for individuals with trauma disorders. Identifying the specific cognitive distortions about the trauma may provide an entrée into autobiographical memory for which the patient experiences amnesia. As the patient becomes able to correct cognitive distortions, particularly about the meaning of prior trauma, a more detailed recall of traumatic events may occur.

HYPNOSIS. Hypnotic interventions can help to contain, modulate, and titrate the intensity of symptoms; to facilitate controlled recall of dissociated memories; to provide support and ego strengthening for the patient; and, finally, to promote working through and integration of dissociated material.

Also, the patient can learn self-hypnosis to apply containment and calming techniques in his or her everyday life. Successful use of containment techniques, whether hypnotically facilitated or not, also increases the patient's sense that he or she can more effectively be in control of alternations between intrusive symptoms and amnesia.

GROUP PSYCHOTHERAPY. Time-limited and longer-term group psychotherapies can help combat veterans with PTSD and survivors of childhood abuse. During group sessions, patients may recover memories for which they have had amnesia. Supportive interventions by the group members or the group therapist, or both, may facilitate integration and mastery of the dissociated material.

Somatic Therapies. No known pharmacotherapy exists for dissociative amnesia other than pharmacologically facilitated interviews. The interviews have used a variety of sedatives, including sodium amobarbital, thiopental, oral benzodiazepines, and amphetamines.

Pharmacologically facilitated interviews using intravenous amobarbital or diazepam are used primarily in working with acute amnesias and conversion reactions, among other indications, in general hospital medical and psychiatric services. This procedure is also occasionally useful in refractory cases of chronic dissociative amnesia when patients are unresponsive to other interventions. The material uncovered in a pharmacologically facilitated interview needs to be processed by the patient in his or her usual conscious state. The Joint Commission now considers pharmacologically facilitated interviews to be conscious sedation, requiring the presence of an anesthesiologist.

Depersonalization/Derealization Disorder

Clinicians working with patients with depersonalization/derealization disorder often find them to be a singularly clinically refractory group. However, benzodiazepines, serotonin reuptake inhibitors, and stimulants appear to be partially efficacious for some patients. There is absolutely no empirical evidence for the efficacy of typical or atypical antipsychotic medications in depersonalization/derealization disorder, and indeed these medications may increase a feeling of emotional deadness and lack of

emotional response to oneself or the world. Also, opioid antagonists such as naltrexone and cognitive enhancers have had some benefit in the clinical treatment of specific depersonalization/derealization disorder patients. Early data suggest the possible efficacy of repetitive transcranial magnetic stimulation (rTMS) treatment.

Many different types of psychotherapy may help depersonalization disorder: psychodynamic, cognitive, cognitive-behavioral, hypnotherapeutic, and supportive. However, the response is not robust for many patients. Stress management strategies, distraction techniques, reduction of sensory stimulation, relaxation training, and physical exercise may be somewhat helpful in some patients.

Dissociative Identity Disorder

Psychotherapy. The current model of treatment of the dissociative identity disorder patient follows a phasic model that is the current standard of care for complex posttraumatic disorders. The phases include: (1) development of safety and symptom stabilization; (2) (optionally) focused, in-depth attention to traumatic material; and (3) integration or reintegration, in which the individual moves away from a life adaptation based on chronic traumatization and victimization. These phases are relatively heuristic, and aspects of each may be part of the others.

STAGE 1 PHASIC TRAUMA TREATMENT: STABILIZATION AND SAFETY. Stabilization of the individual with dissociative identity disorder is vital to the successful negotiation of all aspects of treatment. Stabilization focuses on the safety and management of core dissociative identity disorder and comorbid symptoms. The majority of patients with dissociative identity disorder come to treatment because of overwhelming PTSD and dissociative symptoms and because of some form of self-destructive behavior or violence against others.

Before establishing safety, the patient in reality or symbolically lives in a world of ongoing trauma, whether perpetrated on the patient by others or by the patient on him/herself due to chronic forms of repeated self-destruction and high-risk behavior. The clinician must logically prioritize basic life and health over other interventions. The clinician may need to resort to many different levels and types of interventions to protect the patient, including

hospitalization, specialized substance use or eating disorders programs, police assistance and shelter for victims of intimate partner violence, social service interventions to protect minor children, and assistance with housing, and access to medical care.

STAGE 2 PHASIC TRAUMA TREATMENT: WORK ON TRAUMATIC MEMORIES. For patients who stabilize and form a reasonable working alliance in treatment, longer-term treatment goals involve the detailed, affectively intense, psychotherapeutic processing of life experiences, and the transformation of the meaning of these experiences for the individual. Authorities emphasize that, in most cases, intensive, detailed psychotherapeutic work with traumatic memories should only start after the patient has demonstrated the ability to use symptom management skills independently, after the self-state system can work together in a reasonably cooperative way, and after a stable therapeutic relationship has been established.

The patient should be able to give informed consent and have a realistic understanding of the potential risks and benefits of intensive focus on traumatic material. Potential risks may include temporary, acute worsening of PTSD, affective, somatoform, and self-destructive symptoms, and short-term interference with daily activities. Long-term benefits may include significant amelioration of dissociative and PTSD symptoms, decreases in subjective self-division, the fusion of identities, and freeing of psychological energy for daily life. The patient must be able to understand that the goal is the integration of dissociated thoughts, feelings, recollections, and perceptions, not the exhumation or expulsion of memories per se.

The patient should not be in the midst of an acute life crisis or significant life change. Also, we should first stabilize comorbid medical and psychiatric disorders. The patient should have the ego strength and psychosocial resources to withstand the rigors of the process, and there must be adequate resources, such as support by significant others, and, potentially, support for additional sessions.

Experienced clinicians attempt to carefully structure affectively intense sessions focused on traumatic material, with attention to affect modulation, restabilization of the patient before concluding the session, and reasonable availability to assist the patient supportively between sessions. It may require many sessions to fully explicate the cognitive and emotional meaning of

traumatic events, so that they may become part of the patient's repertoire of nondissociated, ordinary memories for life experience.

STAGE 3 PHASIC TRAUMA TREATMENT: FUSION, INTEGRATION, RESOLUTION, AND RECOVERY. Throughout treatment, we may observe significant unification of dissociated mental processes. Self-states lose distinctness and decrease compartmentalization of thoughts, memories, and affects. The patient develops a more unified sense of self. Transference is modified, consistent with these changes. Amnesia and switching become less apparent than before. The fusion of states results in the psychological merging of two or more entities at a point in time, with a subjective experience of loss of all separateness. The term *integration* is sometimes used synonymously with *fusion* but is a more general term, describing the process of undoing all forms of dissociative division during treatment. Some patients seem to proceed to a complete fusion of all states. They may shift in self-representation, and develop a consistent and continuous sense of self. Many patients never attain a complete fusion of their personalities but achieve a therapeutic *resolution:* improved communication, collaboration, and cooperation among self-states leading to relative stability and adequate function.

HYPNOSIS. Hypnotherapeutic interventions can often alleviate self-destructive impulses or reduce symptoms, such as flashbacks, dissociative hallucinations, and passive-influence experiences. Teaching the patient self-hypnosis may help with crises outside of sessions. Hypnosis can be useful for accessing specific alter personality states, and their sequestered affects and memories. Hypnosis can create relaxed mental states in which the subject can examine adverse life events without overwhelming anxiety. Clinicians using hypnosis should obtain specialized training in trauma populations. Clinicians should be aware of current controversies over the impact of hypnosis on accurate reporting of recollections and should use appropriate informed consent for its use.

GROUP THERAPY. In therapy groups, including general psychiatric patients, the emergence of alter personalities can be disruptive to the group process by eliciting excess fascination or by frightening other patients. Therapy groups composed only of patients with dissociative identity disorder seem to be more

successful, although the groups must be carefully structured, must provide firm limits, and should generally focus only on here-and-now issues of coping and adaptation.

FAMILY THERAPY. Family or couples therapy is often crucial for long-term stabilization and to address pathologic family and marital processes that are common in patients with dissociative identity disorder and their family members. Education of family and concerned others about dissociative identity disorder and its treatment may help family members cope more effectively with dissociative identity disorder and PTSD symptoms in their loved ones. Group interventions for education and support of family members have also been found helpful. Sex therapy may be a critical part of couples' treatment, because patients with dissociative identity disorder may become intensely phobic of intimate contact for periods, and spouses may have little idea how to deal with this helpfully.

SELF-HELP GROUPS. Patients with dissociative identity disorder usually have a negative outcome to self-help groups or 12-step groups for incest survivors. A variety of problematic issues occur in these settings, including the intensification of PTSD symptoms because of discussion of trauma material without clinical safeguards, exploitation of the patient with dissociative identity disorder by predatory group members, contamination of the patient's recall by group discussions of trauma, and a feeling of alienation even from these other reputed sufferers of trauma and dissociation.

EXPRESSIVE AND OCCUPATIONAL THERAPIES. Expressive and occupational therapies, such as art and movement therapy, have proved particularly helpful in the treatment of patients with dissociative identity disorder. Art therapy may help with the containment and structuring of severe dissociative identity disorder and PTSD symptoms, as well as to permit these patients safer expression of thoughts, feelings, mental images, and conflicts that they have difficulty verbalizing. Movement therapy may facilitate the normalization of body sense and body image for these severely traumatized patients. Occupational therapy may help the patient with focused, structured activities that can be completed successfully and may help with grounding and symptom management.

EYE MOVEMENT DESENSITIZATION AND REPROCESSING. Eye movement desensitization and reprocessing (EMDR) is a treatment for PTSD. No systematic studies have been done in dissociative identity disorder patients using EMDR. Case reports suggest that some dissociative identity disorder patients may be destabilized by EMDR procedures, especially those with acutely increased PTSD and dissociative symptoms. Some authorities believe that EMDR can be a helpful adjunct for later phases of treatment in well-stabilized dissociative identity disorder outpatients. The International Society for the Study of Trauma and Dissociation dissociative identity disorder treatment guidelines suggest that EMDR only be used in this patient population by clinicians who have taken advanced EMDR training, are knowledgeable and skilled in phasic trauma treatment for dissociative disorders and have received supervision in the use of EMDR in dissociative identity disorder.

DIALECTICAL BEHAVIOR THERAPY. Dialectical behavior therapy (DBT) is a treatment developed by the psychologist Marsha Linehan for borderline personality disorder. Its concepts and techniques may be helpful to structure aspects of stabilization throughout dissociative identity disorder treatment since many patients with borderline personality disorder report significant trauma histories and fit the complex trauma construct. Helpfully for the patient with dissociative identity disorder, DBT focuses on the primacy of safety, therapy-interfering behaviors, affect regulation strategies, distress tolerance, and radical acceptance.

However, DBT may also have notable limitations for the patient with a dissociative identity disorder. It does not focus on stabilization and management of dissociative symptoms such as depersonalization/derealization and dissociative amnesia, flashbacks, and unconscious reenactments, traumatic transference, and related trauma-based symptoms.

Psychopharmacologic Interventions.

Guidelines for the use of medications with dissociative patients emphasize the need to identify specific treatment-responsive symptoms rather than attempting to treat the dissociation per se. Medications may help attenuate symptoms to assist the patient in stabilizing during treatment. We should advise patients that the

medication response is likely to be partial, devising the best "shock-absorber" system for the patient at a given time. In general, success is more likely if the target symptoms are present across most or all personality states, rather than confined to one or a few. Because rapid symptom oscillations are characteristic in this population, it is not advisable to chase each symptom shift with a medication change.

The most robust medication treatment effect in this patient population is the response of nightmares to the α_1-adrenergic antagonist prazosin. If the patient tolerates the blood pressure effects, dosages of prazosin as high as 25 mg daily, in single or twice-daily doses, can be useful. Daytime dosing may also be effective for control of flashbacks and intrusive symptoms. Doxazosin, a longer-acting α_1-adrenergic antagonist, may also help with nightmares and intrusive symptoms in PTSD.

Antidepressant medications can reduce depression and stabilize mood. A variety of PTSD symptoms, especially intrusive and hyperarousal symptoms, are partially medication responsive. Clinicians report some success with SSRI, tricyclic, and monoamine oxidase (MAO) antidepressants, β-blockers, clonidine, anticonvulsants, and benzodiazepines in reducing intrusive symptoms, hyperarousal, and anxiety in patients with a dissociative identity disorder. Patients with obsessive-compulsive symptoms may respond to serotonergic antidepressants. Emerging data suggest that naltrexone may help ameliorate recurrent self-injurious behaviors in a subset of traumatized patients.

The atypical neuroleptics, such as risperidone, quetiapine, ziprasidone, aripiprazole, and olanzapine, may be more effective and better tolerated than typical neuroleptics for overwhelming anxiety and intrusive PTSD symptoms in patients with dissociative identity disorder. However, weight gain and metabolic syndrome may be a particularly problematic side effect for these nonpsychotic patients. Occasionally, an extremely disorganized, overwhelmed, chronically ill patient with dissociative identity disorder, who has not responded to trials of other neuroleptics, responds favorably to a trial of clozapine.

Electroconvulsive Therapy. For some patients, ECT helps to ameliorate refractory mood disorders and does not worsen dissociative memory

problems. Clinical experience in tertiary care settings for severely ill patients with dissociative identity disorder suggests that a clinical picture of major depression with persistent, refractory melancholic features across all alter states may predict a positive response to ECT. This response is usually only partial, however, as is typical for most successful somatic treatments in the dissociative identity disorder population.

Table 11-9 lists target symptoms and somatic treatments for dissociative identity disorder.

Dissociative Trance

There are no systematic studies of dissociative trance disorder in the absence of pathologic possession. In general, treatment should focus on the patient understanding the nature of trance states and their relationship to more ordinary phenomena such as daydreaming. Assessment of hypnotizability may also allow the clinician to produce the same symptoms the patient is experiencing with a hypnotic induction. This may lead to an increased sense of control and may be enough to assist the patient in recognizing autohypnotic states and having strategies to manage these. In more chronic cases, supportive–expressive psychotherapy, like that for conversion disorder, may be most successful.

Table 11-9
Medications for Associated Symptoms in Dissociative Identity Disorder

Medications and somatic treatments for posttraumatic stress disorder (PTSD), affective disorders, anxiety disorders, and obsessive-compulsive disorder (OCD)

Selective serotonin reuptake inhibitors (no preferred agent, except for OCD symptoms)

Fluvoxamine (for OCD presentations)

Clomipramine (for OCD presentations)

Tricyclic antidepressants

Monoamine oxidase inhibitors (if patient can reliably maintain diet safely)

Brainwashing

There are no empirical treatment studies of individuals subjected to extreme coercion applied in the service of indoctrination into a belief system or an attempt at identity alteration. The basic principles of phased trauma treatment would seem to provide an organizing framework for their care, as for victims of other forms of torture. Family and social interventions may be necessary because of the duress and disruption accompanying the precipitating events and the social effects of the profound changes in the patient's attitudes, behaviors, and beliefs, as well as sequestration from everyday events during the period of captivity.

Ganser Syndrome

No systematic treatment studies have been conducted, given the rarity of this condition. In most case reports, the patient has been hospitalized and provided with a protective and supportive environment. In some instances,

low doses of antipsychotic medications may be beneficial. Confrontation or interpretations of the patient's approximate answers are not productive, but the exploration of possible stressors may be helpful. Hypnosis and amobarbital narcosynthesis can also help patients reveal the underlying stressors that preceded the development of the syndrome, with the concomitant cessation of the Ganser symptoms.

Usually, a relatively rapid return to normal function occurs within days, although some cases may take a month or more to resolve. The individual is typically amnesic for the period of the syndrome.

EPIDEMIOLOGY

Dissociative Amnesia

Dissociative amnesia is in a range of approximately 2 to 6 percent of the general population. There is no known difference in incidence between men and women. Cases generally begin to be reported in late adolescence and adulthood. Dissociative amnesia can be especially challenging to assess in preadolescent children because of their more limited ability to describe the subjective experience.

Depersonalization/Derealization Disorder

Transient experiences of depersonalization and derealization are prevalent in normal and clinical populations. They are the third most commonly reported psychiatric symptoms, after depression and anxiety. Transient symptoms are common in the general population, with a lifetime prevalence of 26 to 74 percent, and 31 to 66 percent at the time of a traumatic event. Symptoms can occur with the use of illicit drugs, especially marijuana, hallucinogens, ketamine, and 3,4-methylenedioxymethamphetamine (MDMA or Ecstasy). They have been described after certain types of meditation, deep hypnosis, extended mirror or crystal gazing, and sensory deprivation experiences. They are also common after mild to moderate head injury, wherein little or no loss of consciousness occurs, but they are significantly less likely if unconsciousness lasts for more than 30 minutes. Depersonalization/derealization symptoms also occur in patients with epilepsy, both as a manifestation of the aura as well as the seizure itself,

particularly in complex–partial seizure patients. The prevalence of depersonalization/derealization disorder is approximately 2.5 percent, with no age or gender differences.

Dissociative Identity Disorder

Few systematic epidemiologic data exist for dissociative identity disorder. Based on community samples, the prevalence in the general population is approximately 1 to 1.5 percent. Developmental studies indicate that the ratio of female to male dissociative identity disorder cases steadily increases from 1 to 1 in early childhood to approximately 8 to 1 by late adolescence in North American samples.

Ganser Syndrome

The overall frequency of Ganser syndrome has declined with time. Men outnumber women by approximately 2 to 1, and cases have been reported in a variety of cultures. Three of Ganser's first four cases were convicts, leading some authors to consider it to be a disorder of penal populations and, thus, an indicator of potential malingering.

ETIOLOGY

Dissociative Amnesia

In many cases of acute dissociative amnesia, the psychosocial environment out of which the amnesia develops is massively conflictual, with the patient experiencing intolerable emotions of shame, guilt, despair, rage, and desperation. These usually result from conflicts over unacceptable urges or impulses, such as intense sexual, suicidal, or violent compulsions. Traumatic experiences such as physical or sexual abuse can induce the disorder. In some cases, the trauma is caused by a betrayal by a trusted, needed other (betrayal trauma). This betrayal may influence how the event is processed and remembered.

Depersonalization/Derealization Disorder

Psychodynamic. Traditional psychodynamic formulations have

emphasized the disintegration of the ego or have viewed depersonalization as an affective response in defense of the ego. These explanations stress the role of overwhelming, painful experiences or conflictual impulses as triggering events.

Traumatic Stress. A substantial proportion—typically one-third to one-half—of patients in clinical depersonalization case series have histories of significant trauma. Several studies of accident victims find as many as 60 percent of those with a life-threatening experience report at least transient depersonalization during the event or immediately after that. Military training studies find that stress and fatigue can evoke symptoms of depersonalization and derealization and affect performance.

Neurobiologic Theories. There are several neurobiologic theories related to depersonalization and derealization symptoms. These include animal models of *submissive immobility* when an organism determines it is unable to defend itself from a predator, like the concept of "playing dead"; disturbances in inferior bilateral frontal, medial prefrontal, cingulate, insula, and temporoparietal cortex; and neurochemical dysregulation, with various studies implicating the NMDA glutamate receptor, neuropeptide Y, norepinephrine, serotonin, and the opioid system.

Dissociative Identity Disorder

Severe experiences of early childhood trauma are the likely cause of dissociative identity disorder. From 85 to 97 percent of dissociative identify disorder cases reported severe childhood trauma or maltreatment. Physical and sexual abuse are common sources of childhood trauma.

Ganser Syndrome

Some case reports identify precipitating stressors, such as personal conflicts and financial reverses, whereas others note organic brain syndromes, head injuries, seizures, and medical or psychiatric illness. Psychodynamic explanations are common in the older literature; in some cases, there are clear medical or neurologic causes. The physiologic insults from such a disorder may act as acute stressors, precipitating the syndrome in vulnerable

individuals. Some patients have reported significant histories of childhood maltreatment and adversity.

Somatic Symptom and Related Disorders

Everyone experiences somatic symptoms, and most can cope with them effectively. However, some people's lives are overwhelmed by their somatic concerns. Sometimes the somatic concerns stem from well-established major medical illnesses; sometimes, the origins of the concerns are never quite clear. What is common in both situations are the pervasive and overwhelming thoughts and behaviors centered on these sensations. DSM-5 incorporated this perspective because the older perspective (only counting or cataloging symptoms labeled as medically unexplained) embodied in the previous versions of the disorder was unreliable and such perspective often put the doctor and the patient at odds over the question of the legitimacy and "reality" of the patient's symptoms and personal suffering. ICD-10 continues the older approach. However, the planned revision will be more in line with DSM-5.

THE CLINICAL PRESENTATION

Persons suffering from one of these disorders have one or more somatic symptoms that become all-consuming or lead to notable impairment in their day-to-day lives. These symptoms are no longer required to be medically unexplained, as such a distinction in itself is unreliable, and because psychiatrists commonly treat patients with medically established diagnoses who are disproportionately troubled by or preoccupied with their physical symptoms.

Somatic Symptom Disorder

Patients with somatic symptom disorder believe that they have some severe yet undetected disease, and evidence to the contrary does not persuade them otherwise. They may maintain a belief that they have a particular disease or, over time, may transfer their belief to another disease. They are fixated on one or more somatic symptoms that they are convinced are evidence of illness. For some individuals, their convictions persist despite negative laboratory results, the benign course of the alleged disease over time, and appropriate reassurances from physicians. Others may have a genuine medical condition about which they develop excessive and unreasonable anxiety, and this is also a manifestation of somatic symptom disorder. Patients with somatic symptom disorder often experience symptoms of depression and anxiety, in addition to their somatic symptoms.

Illness Anxiety Disorder

Patients with illness anxiety disorder, like those with somatic symptom disorder, believe they have a serious but undiagnosed disease despite evidence to the contrary. They may maintain a belief that they have a particular disease or, as time progresses, they may transfer their belief to another disease. Their convictions persist despite negative laboratory results, the benign course of the alleged disease over time, and appropriate reassurances from physicians. Their preoccupation with illness interferes with their interaction with family, friends, and coworkers. They are often addicted to internet searches about their feared illness, inferring the worst from information (or misinformation) they find there. Unlike somatic symptom disorder, however, these individuals do not have significant physical symptoms. Sometimes people with this disorder develop a fear of going to medical appointments, while other times, they seek excessive reassurance about their health from medical providers.

Conversion Disorder (Functional Neurologic Symptom Disorder)

Persons with conversion disorder (also called functional neurologic symptom disorder) present with what appears to be a neurologic condition. The symptoms may be motor or sensory but are incompatible with known neurologic conditions. Often the illness is preceded by conflicts or other stressors and may seem to be associated with apparent psychological factors.

Individuals with conversion disorder do not intentionally produce these symptoms or deficits. Conversion motor symptoms mimic syndromes such as paralysis, ataxia, dysphagia, or seizure disorder (nonepileptic seizures [NESs]), and the sensory symptoms mimic neurologic deficits such as blindness, deafness, or anesthesia. There can also be disturbances of consciousness (e.g., amnesia, fainting spells).

Psychological Factors Affecting Other Medical Conditions

Patients with this disorder have physical disorders caused by or adversely affected by emotional or psychological factors. A medical condition must always be present to make the diagnosis. Common clinical examples include denial and refusal of treatment for an acute condition (such as myocardial infarct or abdominal emergencies) by individuals with certain personality styles (e.g., domineering or controlling), the exacerbation of asthma or irritable bowel attacks by anxiety, and the manipulation of insulin by an individual with diabetes, or diuretics in the case of hypertensive patients, in efforts to lose weight.

Factitious Disorder

Patients with factitious disorder feign, misrepresent, simulate, cause, induce, or aggravate illness to receive medical attention, regardless of whether or not they are ill. Thus, they may inflict painful, deforming, or even life-threatening injuries on themselves, their children, or other dependents. The primary motivation is not the avoidance of duties, financial gain, or anything concrete. The motivation is simply to receive medical care and to partake in the medical system.

Factitious disorders can lead to significant morbidity or even mortality. Therefore, even the patients falsify their presenting complaints, health professionals must take the medical and psychiatric needs of these patients seriously, as their self-induced symptoms can result in significant harm or even death. Historically this disorder was called "Munchausen syndrome," a reference to the Baron Munchausen, legendary for his outrageously exaggerated stories of his military career.

Other Specified and Unspecified Somatic Symptom and Related

Disorders

Patients with other specified somatic symptom and related disorders present with somatic symptoms that do not meet the threshold for another disorder. For example, they may present with symptoms consistent with illness anxiety disorder, except that the symptoms do not meet the duration criterion; in this case, the diagnosis would be brief illness anxiety disorder.

When there is not enough information to make a specific diagnosis, then clinicians should use the unspecified somatic symptom and related disorder diagnosis.

DIAGNOSIS

Somatic Symptom Disorder

According to the DSM-5, individuals with somatic symptom disorder present with one or more somatic complaints that result in significant angst or functional impairment. Also, they must be anxious about their symptoms or be preoccupied with them. The analogous diagnosis in ICD-10, as well in the previous version of the DSM is somatization disorder. The biggest difference between the two concepts is whether there needs to be evidence that there is no underlying medical cause for the disorder—ICD-10 does, and DSM-IV did require this whereas DSM-5 does not. Table 12-1 compares the approaches to this diagnosis.

Mr. K, a white man in his mid-50s, consulted a general medicine clinic complaining of gastrointestinal problems. He had a long list of physical symptoms and concerns, mostly related to the gastrointestinal system. These included abdominal pain, left lower quadrant cramps, bloating, persistent sense of fullness in stomach hours after eating, intolerance to foods, constipation, decrease in physical stamina, heart palpitations, and feelings that "skin is getting yellow" and "not getting enough oxygen." A review of systems disclosed disturbances from virtually every organ system, including tired eyes with blurred vision, sore throat and "lump" in the throat, heart palpitations, irregular heartbeat, dizziness, trouble breathing, and general weakness.

The patient reported that symptoms started more than 20 years ago. Over this time, psychiatrists, general practitioners, and other medical specialists evaluated him, including surgeons. He used the internet regularly and traveled extensively in search of expert evaluations, seeking new procedures and diagnostic assessments. He had undergone repeated colonoscopies, sigmoidoscopies, and computed tomographic (CT) scans, magnetic resonance imaging (MRI) studies, and ultrasound examinations of the abdomen that had revealed Barrett esophagus but no other pathology. He was on disability and had been unable to work for more than 2 years due to his condition.

About 3 years before his visit to the medical clinic, his abdominal complaints and his fixed belief that he had an intestinal obstruction led to an exploratory surgical intervention for the first time, apparently with negative findings. However, according to the patient, the surgery "got things even worse," and since then, he had undergone at least five more operations. During these surgeries, he has undergone subtotal colectomies and ileostomies due to possible "adhesions" to rule out "mechanical" obstruction. However, available records from some of the surgeries do not disclose any specific pathology other than "intractable constipation." Pathologic specimens were also inconclusive.

A complete physical and neurologic examination showed a well-developed, well-nourished male who was afebrile. A complete physical and neurologic examination was normal except for examination of the abdomen, which revealed multiple abdominal scars. Right ileostomy was present, with soft stool in the bag and active bowel sounds. There was no point tenderness and no abdominal distension. During the examination, the patient kept pointing to an area of "hardness" in the left lower quadrant that he thought was a "tight muscle strangling his bowels." However, the examination did not disclose any palpable mass. Skin and extremities were all within normal limits, and all joints had a full range of motion and no swelling. Musculature was well developed. Neurologic examination was within normal limits. His primary care physician scheduled brief monthly visits by, during which the doctor performed brief physicals, reassured the patient, and allowed the patient to talk about "stressors." The physician avoided invasive tests or diagnostic procedures, did not prescribe any medications and avoided telling the

patient that the symptoms were mental or "all in his head." The primary care physician then referred the patient back to psychiatry.

The psychiatrist confirmed a long list of physical symptoms that started in his 20s, most of which remained medically unexplained. The psychiatric examination revealed some anxiety symptoms, including apprehension, tension, uneasiness, and somatic components such as blushing and palpitations that seemed particularly prominent in social situations. Possible symptoms of depression included mild dysphoria, low energy, and sleep disturbance, all of which the patient blamed on his "medical" problems. The mental status examination showed that Mr. K's mood was rather somber and pessimistic, although he denied feeling sad or depressed. Affect was irritable. He was somatically focused and had little if any, psychological insight. The examination revealed the presence of a few life stressors (unemployment, financial problems, and family issues) that the patient quickly discounted as unimportant. The psychiatrist diagnosed somatic symptom disorder, severe.

Although the patient continued to deny having any psychiatric problems or any need for psychiatric intervention or treatment, he agreed to a few regular visits to continue to assess his situation. He refused to have anyone from his family involved in this process. Efforts to engage the patient with formal therapy such as cognitive-behavioral therapy (CBT) or a medication trial were all futile, so he was seen only for "supportive psychotherapy," with the hope of developing rapport and preventing additional iatrogenic complications.

During the follow-up period, the patient was operated on at least one more time and continued to complain of abdominal bloating and constipation and to rely on laxatives. The patient continued to believe he had an obstruction of his intestines; this bordered on the delusional. However, he continued to refuse pharmacologic treatment. The only medication he accepted was a low-dose benzodiazepine for anxiety. He continued to monitor his intestinal function 24 hr/day and to seek evaluation by prominent specialists, traveling to high-profile specialty centers far from home in search of solutions. (Courtesy of J. I. Escobar, M.D.)

Table 12-1
Somatic Symptom Disorder (DSM-5) and Somatization Disorder (ICD-10)

	DSM-5	ICD-10
Name	**Somatic Symptom Disorder**	**Somatization Disorder**
Duration	≥6 mo	≥2 yr
Symptoms	• Preoccupied with symptoms and their potential seriousness. • Anxious about symptoms and health • Time and energy devoted to the symptoms	• Recurring symptoms • Symptoms frequently change • Prolonged involvement with the medical system • High use of healthcare services
# Symptoms needed	≥1	
Exclusion (not the result of):		Malingering Medical cause for symptoms on workup
Psychosocial impact	Distress or impairment	Social, interpersonal, and familial disruption
Symptom specifiers	With predominant pain	
Severity specifiers	*Mild:* 1 symptom *Moderate:* ≥2 symptoms *Severe:* ≥2 symptoms, with	Undifferentiated somatoform disorder: <2 yr, less severe symptoms Somatoform autonomic

	multiple symptomatic complaints or 1 that is severe	dysfunction: autonomic arousal symptoms or other less specific complaints
		Persistent somatoform pain disorder (pain is the predominant symptom)
Course specifiers	*Persistent:* >6 mo of severe symptoms and impairment	

Although DSM-5 specifies that the symptoms must be present for at least 6 months, transient manifestations can occur after significant stresses, most commonly the death or severe illness of someone important to the patient. It can also occur after a severe illness that resolved but left the patient shaken by the experience. Such states that last fewer than 6 months are diagnosed as "Other Specified Somatic Symptom and Related Disorders" in DSM-5. Transient somatic symptom disorder responses to external stress generally remit with a resolution of the stress, but they can become chronic if friends or healthcare professionals reinforce the concerns.

Illness Anxiety Disorder

The primary DSM-5 diagnostic criteria for illness anxiety disorder are that patients be preoccupied with the false belief that they have or will develop a severe disease in the presence of few if any physical signs or symptoms. With illness anxiety disorder, patients have relatively minor somatic symptoms and instead focus on concerns that they will get sick or have an undiagnosed illness; on the other hand, with somatic symptom disorder, there are significant health concerns along with substantial somatic symptoms. The analogous disorder in ICD-10 and the earlier DSM-IV is hypochondriasis. Table 12-2 compares the two disorders.

Conversion Disorder (Functional Neurologic Symptom Disorder)

A conversion reaction is a rather acute and temporary loss or alteration in

motor or sensory function that requires substantial discordance between the symptoms displayed and any neurologic condition, such that it would be impossible for the patient's presentation to be consistent with a neurologic disease. Because the onset frequently coincides with psychological issues (conflict), early theorists speculated that such issues were "converted" to neurologic symptoms. The problem is that stress is omnipresent in life, and many patients present with conversion without an obvious stressor. The classic syndromes represent neurologic syndromes such as paralysis, seizures, or blindness. In DSM-5, we can indicate the type of symptom the patient is experiencing. Table 12-3 compares the approaches to diagnosing this disorder in DSM-5 and ICD-10. Table 12-4 lists common symptoms of conversion disorder. Table 12-5 lists examples of significant physical examination findings often found in disorder.

Table 12-2
Illness Anxiety Disorder (DSM-5) and Hypochondriasis (ICD-10)

	DSM-5	ICD-10
Name	**Illness Anxiety Disorder**	**Hypochondriacal Disorder**
Duration	≥6 mo	
Symptoms	• Preoccupied with having or getting a serious illness without good reason • Anxious about the belief • Excess health-related behaviors related to the belief ("care-seeking"), maladaptive behaviors, or avoidance behaviors ("care-avoiding")	Preoccupied with having a serious medical illness Anxiety Somatic complaints Concerns about appearance Distress or depression associated

		with the above
# Symptoms needed	All the above	
Exclusion (not the result of):	Another mental disorder	
Symptom specifiers	Care-seeking type Care-avoidant type	
Comments		Body dysmorphic disorder is included with this diagnosis as a subtype

Table 12-3
Conversion Disorder

	DSM-5	ICD-10
Name	**Conversion Disorder (Functional Neurologic Symptom Disorder)**	**Dissociative (Conversion) Disorders**
Symptoms	• ≥ Voluntary motor or sensory symptoms • No correlation between any medical or neurologic illness and the symptoms on examination	
Exclusion (not the result of):	Another mental illness Another medical condition	
Psychosocial impact	Marked distress and/or functional impairment	

Symptom specifiers	**With weakness or paralysis** **With abnormal movement** **With swallowing symptoms** **With speech symptom** **With attacks or seizures** **With anesthesia or sensory loss** **With special sensory symptoms** (i.e., vision, olfaction, hearing) **With mixed symptoms** **Can also specify with or without psychological stressor**	**Dissociative stupor** **Dissociative motor disorder** (limb, speech, or gait) **Dissociative convulsions** **Dissociative anesthesia and sensory loss** **Mixed dissociative (conversion) disorders**
Course specifiers	**Acute episode** (<6 mo) **Persistent** (≥6 mo)	

Mr. J is a 28-year-old single man who works in a factory. He was brought to an emergency department by his father, complaining that he had lost his vision while sitting in the back seat on the way home from a family gathering. He had been playing volleyball at the gathering but had sustained no significant injury except for the volleyball hitting him in the head a few times. He was initially reluctant to play volleyball because of his mediocre athleticism and was a last-minute addition to the team. He recalls having some problems with seeing during the game, but his vision did not become ablated until he was in the car on the way home. By the time he got to the emergency department, his vision was improving, although he still complained of blurriness and mild diplopia. The physician could attenuate the double vision by having the patient focus on different items at different distances.

On examination, Mr. J was fully cooperative, somewhat uncertain

about why this would have occurred, and rather nonchalant. Pupillary, oculomotor, and general sensorimotor examinations were routine. After being cleared medically, the physician referred the patient to a mental health center for further evaluation.

At the mental health center, the patient recounts the same story as he did in the emergency department. His father continued to accompany him. He said his vision improved when his father stopped the car, and they talked about the day's events. He spoke with his father about how he had felt embarrassed and somewhat conflicted about playing volleyball but felt pressure to play. Further history from the patient and his father revealed that this young man had been shy as an adolescent, particularly around athletic participation. He had never had another episode of visual loss. He did recount feeling anxious and sometimes not feeling well in his body during athletic activities.

Discussion with the patient at the mental health center focused on the potential role of psychological and social factors in acute vision loss. The patient was somewhat perplexed by this but was also amenable to discussion. He stated that he recognized that he began seeing and feeling better when his father pulled off to the side of the road and discussed things with him. Doctors stated that they did not know the cause of the vision loss and that it would likely not return. The patient and his father were satisfied with the medical and psychiatric evaluation and agreed to return for care if there were any further symptoms. The patient was appointed a follow-up time at the outpatient psychiatric clinic. (Courtesy of Michael A. Hollifield, M.D.)

Table 12-4
Common Symptoms of Conversion Disorder

Motor Symptoms	Sensory Deficits
Involuntary movements	Anesthesia, especially of extremities
Tics	Midline anesthesia
Blepharospasm	Blindness

Torticollis	Tunnel vision
Opisthotonos	Deafness
Seizures	**Visceral Symptoms**
Abnormal gait	Psychogenic vomiting
Falling	Pseudocyesis
Astasia–abasia	Globus hystericus
Paralysis	Swooning or syncope
Weakness	Urinary retention
Aphonia	Diarrhea

(Courtesy of Frederick G. Guggenheim, M.D.)

Table 12-5
Distinctive Physical Examination Findings in Conversion Disorder

Condition	Test	Conversion Findings
Anesthesia	Map dermatomes	Sensory loss does not conform to recognized pattern of distribution
Hemianesthesia	Check midline	Strict half-body split
Astasia–abasia	Walking, dancing	With suggestion, those who cannot walk may still be able to dance; alteration of sensory and motor findings with suggestion
Paralysis, paresis	Drop paralyzed hand onto face	Hand falls next to face, not on it
	Hoover test	Pressure noted in examiner's

		hand under paralyzed leg when attempting straight leg raising
	Check motor strength	Give-away weakness
Coma	Examiner attempts to open eyes	Resists opening; gaze preference is away from doctor
	Ocular cephalic maneuver	Eyes stare straight ahead, do not move from side to side
Aphonia	Request a cough	Essentially normal coughing sound indicates cords are closing
Intractable sneezing	Observe	Short nasal grunts with little or no sneezing on inspiratory phase; little or no aerosolization of secretions: minimal facial expression; eyes open; stops when asleep; abates when alone
Syncope	Head-up tilt test	Magnitude of changes in vital signs and venous pooling do not explain continuing symptoms
Tunnel vision	Visual fields	Changing pattern on multiple examinations
Profound monocular blindness	Swinging flashlight sign (Marcus Gunn)	Absence of relative afferent pupillary defect
	Binocular visual	Sufficient vision in "bad eye"

	fields	precludes plotting normal physiologic blind spot in good eye
Severe bilateral blindness	"Wiggle your fingers, I'm just testing coordination"	Patient may begin to mimic new movements before realizing the slip
	Sudden flash of bright light	Patient flinches
	"Look at your hand"	Patient does not look there
	"Touch your index fingers"	Even blind patients can do this by proprioception

(Courtesy of Frederick G. Guggenheim, M.D.)

Sensory Symptoms. In conversion disorder, anesthesia and paresthesia are common, especially of the extremities. All sensory modalities can be involved, and the distribution of the disturbance is usually inconsistent with either central or peripheral neurologic disease. Thus, clinicians may see the characteristic stocking-and-glove anesthesia of the hands or feet or the hemianesthesia of the body beginning precisely along the midline.

Conversion disorder symptoms may involve the organs of special sense and can produce deafness, blindness, and tunnel vision. These symptoms can be unilateral or bilateral, but neurologic evaluation reveals intact sensory pathways. In conversion disorder blindness, for example, patients walk around without collisions or self-injury, their pupils react to light, and their cortical-evoked potentials are normal.

Motor Symptoms. The motor symptoms of conversion disorder include abnormal movements, gait disturbance, weakness, and paralysis. Gross rhythmical tremors, choreiform movements, tics, and jerks may be present. The movements generally worsen when calling attention to them. One gait disturbance seen in conversion disorder is *astasia–abasia,* which is a wildly

ataxic, staggering gait accompanied by gross, irregular, jerky truncal movements and thrashing and waving arm movements. Patients with the symptoms rarely fall; if they do, they are generally not injured.

Other common motor disturbances are paralysis and paresis involving one, two, or all four limbs, although the distribution of the involved muscles does not conform to the neural pathways. Reflexes remain normal; the patients have no fasciculations or muscle atrophy (except after long-standing conversion paralysis); electromyography findings are normal.

Seizure Symptoms. NESs are another symptom of conversion disorder. Clinicians may find it challenging to differentiate NESs from an actual seizure by clinical observation alone. Some patients with NESs also have a coexisting epileptic disorder, which may complicate the clinical picture. Tongue-biting, urinary incontinence, and injuries after falling can occur in NESs, although these symptoms are generally not present. Patients with NESs retain pupillary and gag reflexes after their seizure-like activity, and patients have no postseizure increase in prolactin concentrations.

Other Associated Features. Several psychological symptoms are also associated with conversion disorder.

PRIMARY GAIN. Patients achieve primary gain by keeping internal conflicts outside their awareness. Symptoms have symbolic value; they represent an unconscious psychological conflict.

SECONDARY GAIN. Patients accrue tangible advantages and benefits as a result of being sick; for example, being excused from obligations and difficult life situations, receiving support and assistance that might not otherwise be forthcoming, and controlling others' behavior.

LA BELLE INDIFFÉRENCE. *La belle indifférence* ("beautiful indifference") is a patient's inappropriately cavalier attitude toward severe symptoms; that is, the patient seems to be unconcerned about what appears to be a significant impairment. That bland indifference may also occur in some seriously ill medical patients who develop a stoic attitude. The presence or absence of *la belle indifférence* is not pathognomonic of conversion disorder, but it is often

associated with the condition.

IDENTIFICATION. Patients with conversion disorder may unconsciously model their symptoms on those of someone important to them. For example, a parent or a person who has recently died may serve as a model for conversion disorder. During pathologic grief reaction, bereaved persons commonly have symptoms of the deceased.

Psychological Factors Affecting Other Medical Conditions

According to DSM-5, individuals with this condition have a medical illness that is significantly impacted by psychological influences or patterns of behavior. We should only make the diagnosis when the effect of the psychological issue on the medical condition is unambiguous and leads to documentable effects on the course and outcome of the medical condition. Psychological or behavioral factors include psychological distress, patterns of interpersonal interaction, coping styles, and maladaptive health behaviors such as denial of symptoms or poor adherence to medical recommendations.

The reverse situation, the psychiatric or psychological consequences of having a medical condition, is more appropriately classified as an adjustment disorder. Other ambiguous situations where psychological and physical symptoms coexist (the so-called "comorbidities") present particular challenges. For example, many somatic, anxiety, and mood disorders are associated with chronic medical conditions (diabetes, hypertension, hypercholesterolemia) or "functional" syndromes (irritable bowel, migraine headaches, and several others).

Mr. A, a 55-year-old man, was hospitalized in the intensive care unit following a cardiac arrest. He had been experiencing severe substernal chest pain but "ignored it." He became diaphoretic and reported reluctantly to a nearby emergency room where he had a cardiac arrest while awaiting evaluation. He was successfully resuscitated and transferred to the ICU. He emphatically rejected having had a heart attack, took his EKG leads off, and was preparing to leave the unit against medical advice. The psychiatric consultant obtained a history that the patient's father and his brother had died of coronary disease. At the

time of the initial assessment, the patient was irritable and somewhat anxious. He agreed to stay in the ICU overnight after his wife insisted that he stay, and the psychiatrist explained the tests further. The psychiatrist prescribed a low dose of a benzodiazepine, and, on the next day, he was agreeable to remain in the hospital for further treatment.

Factitious Disorder

Factitious disorder is the faking of physical or psychological signs and symptoms. Symptoms can be imposed on self or imposed on another. Table 12-6 compares criteria for the disorder and Table 12-7 list some clues that should trigger suspicion of this disorder.

Factitious Disorder Imposed on Self. We diagnose this condition when an individual feigns having a medical or psychiatric illness in order to achieve the sick role. Patients may simply misrepresent their symptoms, may cause injury to themselves, or may use other dishonest methods in order to appear as if they are sick.

Some patients show psychiatric symptoms judged to be fake. This determination can be difficult and is often made only after a prolonged investigation. The feigned symptoms frequently include depression, hallucinations, dissociative and conversion symptoms, and bizarre behavior. Because the patient's condition does not improve after routine therapeutic measures, he or she may receive large doses of psychoactive drugs and may undergo electroconvulsive therapy. Patients may appear depressed and may explain their depression by offering a false history of the recent death of a significant friend or relative. Elements of the history that may suggest factitious bereavement include a violent or bloody death, a death under dramatic circumstances, and the dead person being a child or a young adult. Other patients may describe either recent and remote memory loss or both auditory and visual hallucinations. Some patients may use psychoactive substances to produce symptoms, such as stimulants to produce restlessness or insomnia, or hallucinogens to produce distortions of reality. Combinations of psychoactive substances can produce very unusual presentations. Other psychological symptoms include pseudologia fantastica and impostorship.

Table 12-6
Factitious Disorder

	DSM-5	ICD-10
Name	**Factitious Disorder**	**Intentional Production or Feigning of Symptoms or Disabilities, Either Physical or Psychological (Factitious Disorder)**
Symptoms	**Factitious disorder imposed on self:** • Fabricates their symptoms and clinical findings • Claims to be ill • Purposely misleads health professionals • No apparent external reward or motivation (outside of the illness role) **Factitious disorder imposed on another:** • As above except the object of the feigned illness or injury is another person.	Feigns symptoms No apparent external reward or motivation Aim is to take on the sick role
Exclusion (not the result of):	Another mental disorder	Factitious dermatitis Malingering
Course	**Single episode**	

specifiers	**Recurrent episodes** (2 or more discrete events)
Comments	*Note: In factitious disorder imposed on another, the perpetrator receives the diagnosis, not the victim.*

Table 12-7
Clues That Should Trigger Suspicion of Factitious Disorder

1. The patient has sought treatment at various different hospitals or clinics
2. The patient is an inconsistent, selective, or misleading informant; he or she resists allowing the treatment team access to outside sources of information
3. The course of the illness is atypical and does not follow the natural history of the presumed disease
4. A remarkable number of tests, consultations, and medical and surgical treatments have been done to little or no avail
5. The magnitude of symptoms consistently exceeds objective pathology or symptoms have proved to be exaggerated by the patient
6. Some findings are discovered to have been self-induced or at least worsened through self-manipulation
7. The patient might eagerly agree to or request invasive medical procedures or surgery
8. Physical evidence of a factitious cause might be discovered during the course of treatment
9. The patient predicts deteriorations or there are exacerbations shortly before their scheduled discharge

10. A diagnosis of factitious disorder has been explicitly considered by at least one healthcare professional
11. The patient is noncompliant with diagnostic or treatment recommendations or is disruptive on the unit
12. Evidence from laboratory or other tests disputes information provided by the patient
13. The patient has a history of work in the healthcare field
14. The patient engages in gratuitous, self-aggrandizing lying
15. The patient has been prescribed (or obtained) opiate drugs when not indicated
16. While seeking medical or surgical intervention, the patient opposes psychiatric assessment

In *pseudologia fantastica,* the patient mixes limited factual material with extensive and colorful fantasies. The listener's interest pleases the patient and, thus, reinforces the symptom. In addition to distortions of the history, patients often give false and conflicting accounts about other areas of their lives (e.g., they may claim the death of a parent, to play on the sympathy of others). Imposture is commonly related to lying in these cases. Many patients assume the identity of a prestigious person. They may, for example, report being war heroes and attribute their surgical scars to wounds received during battle or in other dramatic and dangerous exploits. Similarly, they may say that they have ties to accomplished or renowned figures.

Other patients may feign physical symptoms suggesting a disorder involving any organ system. They are familiar with the diagnoses of most disorders that usually require hospital admission or medication and can give excellent histories capable of deceiving even experienced clinicians. Clinical presentations are myriad and include hematoma, hemoptysis, abdominal pain, fever, hypoglycemia, lupus-like syndromes, nausea, vomiting, dizziness, and seizures. For example, the patient may contaminate urine with blood or feces or take anticoagulants to simulate bleeding disorders, or insulin to produce hypoglycemia. Such patients often insist on surgery and claim adhesions from previous surgical procedures. They may acquire a "gridiron" or washboard-like abdomen from multiple procedures. Complaints of pain, especially that simulating renal colic, are common, with the patients wanting

narcotics. In about half the reported cases, these patients demand treatment with specific medications, usually analgesics. Once in the hospital, they continue to be demanding and challenging. After each test result is negative, they may accuse doctors of incompetence, threaten litigation, and become generally abusive. Some may sign out abruptly shortly before they believe the healthcare team is going to confront them with their factitious behavior. They then go to another hospital in the same or another city and begin the cycle again. Specific predisposing factors are actual physical disorders during childhood, leading to extensive medical treatment. Other factors may include a grudge against the medical profession, employment in the healthcare industry, or a significant relationship with a physician in the past.

Table 12-8 provides a comprehensive overview of a variety of signs and symptoms that may be faked and mistaken for genuine illness. The table also includes the means of simulation and possible methods of detection.

Factitious Disorder Imposed on Another (formerly Factitious Disorder by Proxy). In this diagnosis, a person intentionally produces physical signs or symptoms in another person who is under the first person's care. One apparent purpose of the behavior is for the caretaker to assume the sick role indirectly; another is to be relieved of the caretaking role by having the child hospitalized. The most common cause of factitious disorder imposed on another involves a mother who deceives medical personnel into believing that her child is ill. The deception may involve a false medical history, contamination of laboratory samples, alteration of records, or induction of injury and illness in the child. Table 12-9 lists some clues that should trigger suspicion of this disorder.

BC, a 1-month-old girl, was admitted for the evaluation of fever. The medical team requested a psychiatric consult because of inconsistencies in the mother's reporting of medical information despite her presentation as a knowledgeable and caring mother who worked as an emergency medical technician. BC's mother reported her own diagnosis of ovarian cancer when she was 3 months pregnant with BC. She reported undergoing a hysterectomy during her cesarean section, and that she had been getting radiation therapy at a local hospital since BC's birth. The

pediatrician called the local hospital with the mother's permission and learned that she had a corpus luteum cyst removed at 3 months' gestation and mild hydronephrosis but no cancer or hysterectomy. BC's mother, when confronted with this, replied that she might need a kidney transplant for the hydronephrosis.

On further exploration, the medical team discovered that the mother had brought her children to multiple emergency rooms, giving inaccurate histories that prompted excessive testing. At one visit, she told clinicians that her 2-year-old son had lupus and hypergammaglobulinemia, and at another visit, that he had asthma and seizures. She also pursued a minor cosmetic surgical procedure for him against his pediatrician's recommendation.

Clinicians suspected that BC's mother intentionally fabricated symptoms, such as by warming BC's thermometer, and that she did not actively induce symptoms in her children. She was faithful in keeping medical appointments, and her children appeared healthy and well cared for, despite her factitious behavior. The mother denied a psychiatric history but agreed to let the clinicians contact the local psychiatric hospital. That hospital revealed her history of depression, anorexia, panic disorder, and a suicide attempt resulting in psychiatric hospitalization. After the hospitalization, she received psychotherapy and medication, which she stopped a few months before this presentation. During BC's admission for fever, her mother agreed to resume psychiatric treatment. The team made a referral to social services, and the pediatrician scheduled regular follow-up visits for the children.

Table 12-8
Methods of Factitious Symptom Production, Suggestive Signs, and Confirmatory Tests by Systems

Symptom	Method of Factitious Symptom Manufacture	Signs Suggestive Factitiousness
Infectious Disease		
Fever	Injecting infectious material	Higher than 41°C

	into vein/intravenous line	
	Ingesting thyroid hormone	Not accompanied b[y?] other vital sign abnormalities
	Drinking hot fluids	Does not follow diur[nal?] pattern
	Manipulating thermometers with lightbulb or heating pad	No diaphoresis with defervescence
	Substituting another thermometer	
	Warm wax/wet cotton in ears	Measuring fresh uri[ne?] specimen tempe[rature?]
Bacteremia	Injection of contaminated substance	Polymicrobial bacte[remia?]
		Absence of urologic/biliary/G[I?] obstruction
		Stool flora/pet flora
HIV/AIDS	False history/reports	Normal CD4 count/undetecta[ble?] viral load/Ab neg[ative?]
Gastrointestinal		
Diarrhea	Laxative abuse (magnesium, castor oil, phenolphthalein)	Metabolic alkalosis

		Acute hyperchlorem... metabolic acidos... with normal anio...
		Decreased serum bicarbonate with metabolic acidos...
		High daily stool volu...
		Melanosis coli on sigmoidoscopy
		Cathartic colon on l... enema
		Low urine potassiu... concentration
		High fecal fluid pota... concentration
		Fecal fluid osmolali... <290 mOsm/kg
	Adding water to stool sample	High stool osmolar ... >125 mOsmol/k...
Vomiting	Ipecac/cathartic abuse	Hypokalemia
		High urine potassiu... concentration
		Low urine chloride concentration
		Metabolic alkalosis ... increased serum bicarbonate

Pancreatitis	Spitting into urine sample (salivary amylase)	Hyperamylasuria w normal serum amylase
GI bleeding	Injection of blood from transfusions	Nasogastric tube sr blood despite no endoscopy
	Ingestion of NSAIDs/salicylates	Single-stripe sign o colonoscopy
Obstruction	Ingestion of loperamide	

Renal

Diuresis	Diuretic abuse	High urine potassiu concentration
Bartter syndrome	Loop diuretic abuse	Hypokalemia, urine chloride low or variable
	Self-induced vomiting	

Metabolic

Hypervitaminosis A	Vitamin A abuse	Increased gamma-glutamyltransfer; Increased bilirubin
Hypokalemia	Laxative abuse	See above
Hyperkalemia	Injection of urine into blood sample	Potassium level incompatible wit
Hypernatremia	Salt load	Fractional excretion sodium high
		Gastric aspirate sal concentration >2 mmol/L

Urologic

Hematuria	Adding blood from another wound/meat	Lack of red blood cell/hemoglobin
	Traumatizing urethra	Lack of distorted re blood cells
	Inserting foreign bodies into the bladder	
	Ingestion of anticoagulants	
	Addition of coloring to urine	
Proteinuria	Injection of egg protein in bladder	Large day-to-day variations in urin protein concentr
		Serum albumin concentration re in normal range
		Lack of other signs nephrotic syndro
Bacteriuria	Injecting bacteria into bladder or urine specimens	
Urinary calculi	Adding pepper grains to urine	
	Inserting stones into bladder	
	Submitting quartz, feldspar as samples	

Hematologic

Anemia	Self-bloodletting	Decreased serum ir ferritin, iron-bind capacity
		Decreased bone m. iron concentratic
		No evidence of blee
Sickle cell crisis		Serum protein electrophoresis normal
Pancytopenia	Ingestion of chemotherapy	
Hemorrhage/purpura	Ingestion of anticoagulant (rodenticide/Coumadin)	Prolonged prothron time (PT)
	Heparin injection	Prolonged partial thromboplastin t (PTT) with norm
	Ingestion of quinidine	Purpura with thrombocytopen

Endocrine

Hypoglycemia	Injection of insulin	Serum insulin

	Ingestion of oral hypoglycemic (sulfonylurea)	concentration >1 mU/L
	Ingestion of tolbutamide	
	Manipulation of testing strips	
Hyperglycemia	Insufficient administration of insulin	
Hyperthyroidism	Ingestion of thyroid hormone	Goiter/eye findings absent
		Increased thyroxine liothyronine leve
		Low TSH in thyroid
Cushing syndrome	Injecting/ingesting glucocorticoid	Plasma/urinary cort increased
	Adding glucocorticoid to urine	Plasma ACTH low/undetectable
		Normal corticosterone/h cortisol

Pheochromocytoma	Injection of epinephrine, isoproterenol	Normal chromograr level
	Ingestion of stimulant	Lack of metabolites epinephrine (metanephrines)
	Injection of epinephrine into urine sample	Lack of norepineph increase after glucagon
		Normal response to clonidine suppre test
Hyperaldosteronism	Ingestion of black licorice/glycyrrhizic acid	Treatment-resistant hypokalemia
		Metabolic alkalosis
		Hypernatremia
Cardiovascular		
Arrhythmia	Rearranging of EKG leads Ingestion of digitalis, beta blockers, calcium channel blockers	Unusual pattern on
Hypertension	Valsalva maneuver	Office BPs normal, BPs high
	Ingestion of stimulants	
Infarction	Beating self with towel to raise creatine kinase	EKGs don't change
		Enzymes do not ris appropriately

Dermatologic

Cheilitis granulomatosa	Self-inoculation with polyvinylpyrrolidone (PVP)	
Dermatitis artefacta	Self-mutilation	Distribution of lesio... reachable areas
Erythematous lesion	Applying alcohol to lesion	
Nonhealing wounds	Injection of air/contaminants/foreign bodies	Heal when casted Resistant to treatme... Subcutaneous emphysema

Obstetrical

Ectopic pregnancy	Injection of hCG	Negative urine b-hC... Widely varying b-hC... levels
Vaginal discharge	Intravaginal insertion	Inconsistent pH Vaginal wall shows abrasion/denies intercourse

Neurologic

Movement disorders	Ingestion of neuroleptics to induce parkinsonism	MRI/EEG/EMG inconsistent Hoover sign/tremor entrainable/distr... Prolactin elevated v... antipsychotics
Multiple sclerosis		Examination incons...
Pseudoseizures		History inconsistent

		Semiology inconsis...
		Never observed sei... by others
Pulmonary		
Asthma	Tape interfering with pulse oximeters	Intractable hypoxia
	Inhalation of irritant (talc)	Intractable status asthmaticus
	Ingestion of allergens	
Cystic fibrosis	Manipulation of sweat test	Normal x-rays
		Normal examinatior... of clubbing
Hemoptysis	Ingestion of anticoagulants	Normal bronchoscopy/la... blood
	Cough abrasion of lung	
	Self-induced trauma to respiratory tract	
Respiratory failure		Incongruous arteria... blood gas

Anisocoria	Instillation of atropine eye drops	

▲ **Table 12-9**
Clues Triggering Suspicion for Factitious Disorder Imposed on Another Person

1. Diagnosis does not match the objective findings
2. Signs or symptoms are bizarre
3. Caregiver or suspected offender does not express relief or pleasure when told that dependent is improving or that dependent does not have a particular illness

4. Inconsistent histories of symptoms from different observers
5. Caregiver insists on invasive or painful procedures or hospitalizations
6. Caregiver's behavior does not match expressed distress or report of symptoms (e.g., unusually calm)
7. Signs and symptoms begin only in the presence of one caregiver
8. Sibling or another dependent has or had an unusual or unexplained illness or death
9. Sensitivity to multiple environmental substances or medicines
10. Failure of the dependent's illness to respond to its normal treatments or unusual intolerance to those treatments
11. Caregiver publicly solicits sympathy or donations or benefits because of the dependent's rare illness
12. Extensive unusual illness history in the caregiver or caregiver's family; caregiver's history of somatization disorders
13. Caregiver seeks other medical opinions when told the dependent does not have illness
14. Caregiver perseverates about borderline abnormal results of no clinical relevance despite repeated reassurance, or refutes the validity of normal results

Other Specified or Unspecified Somatic Symptom and Related Disorders

This DSM-5 category describes conditions characterized by one or more unexplained physical symptoms, which are below the threshold for a diagnosis of somatic symptom or a related disorder. The symptoms are not better explained solely by another medical, psychiatric, or substance use disorder, and they cause clinically significant distress or impairment. Disorders in this category generally have too few symptoms are too brief to meet the criteria for a full disorder.

EVALUATION OF SOMATIC SYMPTOM AND RELATED DISORDERS

Patients with severe and protracted somatic syndromes approach medical

encounters with a mixture of unrealistic expectations, pessimism, and distrust of the medical profession. The patients base these attitudes on their previous experiences with physicians, in which the physicians showed a lack of interest or disbelief in the patient's complaints and suffering. Building a trusting alliance must begin with respect for the patient's symptoms and an acknowledgment of their validity. Active, receptive listening, tolerance for repetition, and a "neutral" approach (avoiding being dismissive, confrontational, or overly reassuring) are essential skills.

Many of these patients often bring "thick" charts that include descriptions of many clinical encounters and multiple tests and procedures that are redundant and ordered without a clear rationale. The prospect of reviewing these medical records is challenging and often leads to a negative attitude from the physician. The physician should keep an open mind, despite forewarnings in the medical records, and perform an independent assessment of the patient. Avoid an emphasis on psychological questioning and interpretations at this stage. The patient may perceive premature reassurance as disinterest or dismissiveness.

Many patients with somatic symptom and related disorders do not readily acknowledge or recognize "emotional" issues and will feel more comfortable dealing with questions related to their physical symptoms than questions related to psychological issues. Taking a history of multiple somatic complaints can be carried over into subsequent appointments. A thorough physical examination, including neurologic examination, should follow history-taking at the initial visit, and the clinician should perform briefer physical assessments at subsequent visits. An inclusive drug history, including prescription and nonprescription remedies, should also be completed. As history-taking moves along, attitudes, beliefs, and attributions should become more evident and patterns of interaction and illness behavior discernible.

In the case of conversion disorder, there should be careful attention to any history of trauma, sexual abuse, physical abuse, and family history of conversion symptoms. Additionally, a neurologic workup of suspected conversion disorder should include routine laboratory studies, electroencephalograms, and other special studies (such as MRI) to rule out organic causes.

In the case of factitious disorder, the psychiatric examination should

emphasize securing information from any available friends, relatives, or other informants, because interviews with reliable outside sources often reveal the false nature of the patient's illness. Although time-consuming and tedious, corroborating all the facts presented by the patient about previous hospitalizations and medical care is essential. Psychiatric evaluation is requested on a consultation basis in about 50 percent of cases, usually after a simulated illness is suspected. Under these circumstances, it is necessary to avoid pointed or accusatory questioning that may provoke truculence, evasion, or flight from the hospital. A danger may exist in provoking frank psychosis when using vigorous confrontation. In some instances, the feigned illness serves an adaptive function and is a desperate attempt to ward off further disintegration.

DIFFERENTIAL DIAGNOSIS

Somatic Symptom Disorder

We should differentiate somatic symptom disorder from nonpsychiatric medical conditions, especially disorders that show symptoms that are not necessarily easily diagnosed. Such diseases include acquired immunodeficiency syndrome (AIDS), endocrinopathies, myasthenia gravis, multiple sclerosis, degenerative diseases of the nervous system, systemic lupus erythematosus, and occult neoplastic disorders.

Somatic symptom disorder is differentiated from illness anxiety disorder by the emphasis on illness anxiety disorder on fear of having a disease rather than a concern about many symptoms. Patients with illness anxiety disorder usually complain about fewer symptoms than patients with somatic symptom disorder; they are primarily concerned about being sick.

Conversion disorder is acute and generally transient and usually involves a symptom rather than a particular disease. The presence or absence of *la belle indifférence* is an unreliable feature with which to differentiate the two conditions.

Patients with body dysmorphic disorder wish to appear normal, but believe that others notice that they are not, whereas those with somatic symptom disorder seek out attention for their presumed diseases.

Somatic symptom disorder can also occur in patients with depressive

disorders and anxiety disorders. Patients with panic disorder may initially complain that they are affected by a disease (e.g., heart trouble), but careful questioning during the medical history usually uncovers the classic symptoms of a panic attack. Delusional beliefs occur in schizophrenia and other psychotic disorders but can be differentiated from somatic symptom disorder by their delusional intensity and by the presence of other psychotic symptoms. Also, schizophrenic patients' somatic delusions tend to be bizarre, idiosyncratic, and out of keeping with their cultural milieus, as illustrated in the case below.

> A 52-year-old man complained, "my guts are rotting away." Even after an extensive medical workup, the physician could not reassure the man that he was not ill.

Somatic symptom disorder is distinguished from factitious disorder and from malingering in that patients with somatic symptom disorder experience and do not simulate the symptoms they report.

Illness Anxiety Disorder

Again, we must differentiate illness anxiety disorder from other medical conditions. Too often, doctors dismiss these patients as "chronic complainers" and do not perform a careful medical examination. Patients with an illness anxiety disorder are differentiated from those with somatic symptom disorder by the emphasis on illness anxiety disorder on fear of having a disease versus the emphasis on somatic symptom disorder on concern about many symptoms. However, both may exist to varying degrees in each disorder. Patients with illness anxiety disorder usually complain about fewer symptoms than patients with somatic symptom disorder. Conversion disorder is differentiated from illness anxiety disorder by the fact that it is acute, generally transient, and usually involves a symptom rather than a particular disease. The fear of illness can also occur in patients with depressive and anxiety disorders. If a patient meets the full diagnostic criteria for both illness anxiety disorder and another major mental disorder, such as major depressive disorder or generalized anxiety disorder, the patient should

receive both diagnoses. Illness anxiety disorder can be differentiated from obsessive-compulsive disorder by the singularity of their beliefs and by the absence of compulsive behavioral traits, but there is often an obsessive quality to the patient's fear. Delusional beliefs can be differentiated from illness anxiety disorder by their delusional intensity and the presence of other psychotic symptoms.

Conversion Disorder (Functional Neurologic Symptom Disorder)

One of the significant problems in diagnosing conversion disorder is the difficulty in definitively ruling out a medical disorder. Concomitant nonpsychiatric medical disorders are common in hospitalized patients with conversion disorder, and evidence of a current or previous neurologic disorder or a systemic disease affecting the brain occurs in 18 to 64 percent of such patients. An estimated 25 to 50 percent of patients classified as having conversion disorder eventually receive diagnoses of neurologic or nonpsychiatric medical disorders that could have caused their earlier symptoms. Thus, a thorough medical and neurologic workup is essential in all cases. If the suggestion resolves the symptom, such as with hypnosis, or parenteral amobarbital or lorazepam, the symptoms are probably the result of conversion disorder.

Neurologic disorders (e.g., dementia and other degenerative diseases), brain tumors, and basal ganglia disease are part of the differential diagnosis. For example, weakness may be confused with myasthenia gravis, polymyositis, acquired myopathies, or multiple sclerosis. Optic neuritis can resemble conversion disorder blindness. Other diseases that can cause confusing symptoms are Guillain–Barré syndrome, Creutzfeldt–Jakob disease, periodic paralysis, and early neurologic manifestations of AIDS. Conversion disorder symptoms occur in schizophrenia, depressive disorders, and anxiety disorders, but these other disorders are associated with their distinct symptoms that eventually make differential diagnosis possible.

The demarcation between conversion disorder and somatic symptom disorder is not that clear, and conversion symptoms may form part of the constellation of symptoms seen in somatic symptom disorder. One differentiating feature is that conversion disorder requires that the presenting symptoms be inconsistent with neurologic conditions, whereas somatic

symptom disorder does not require this inconsistency.

In both malingering and factitious disorder, the symptoms are under conscious, voluntary control. A malingerer's history is usually more inconsistent and contradictory than that of a patient with conversion disorder, and a malingerer's fraudulent behavior is goal-directed.

Psychological Factors Affecting Other Medical Conditions

Differential diagnosis can be complicated and should include other somatic symptom disorders (somatic symptom disorder, conversion disorder, factitious disorder) as well as personality disorders (e.g., borderline personality disorder).

Factitious Disorder

Any disorder in which physical signs and symptoms are prominent are part of the differential diagnosis, and the physician must explore the possibility of authentic or concomitant physical illness. Additionally, a history of many surgeries in patients with factitious disorder may predispose such patients to complications or actual diseases, necessitating even further surgery. Factitious disorder is on a continuum between somatic symptom and related disorders and malingering, the goal being to assume the sick role.

A factitious disorder is differentiated from conversion disorder by the voluntary production of factitious symptoms, the extreme course of multiple hospitalizations, and the seeming willingness of patients with a factitious disorder to undergo an extraordinary number of mutilating procedures. Patients with conversion disorder are not usually conversant with medical terminology and hospital routines, and their symptoms have a direct temporal relation or symbolic reference to specific emotional conflicts.

Illness anxiety disorder differs from factitious disorder in the lack of voluntary production of symptoms.

Because of their pathologic lying, lack of close relationships with others, hostile and manipulative manner, and associated substance use and criminal history, clinicians may think that patients with factitious disorder have an antisocial personality disorder. Antisocial persons, however, do not usually volunteer for invasive procedures or resort to a way of life marked by repeated or long-term hospitalization. Because of attention-seeking and an

occasional flair for the dramatic, they may also be diagnosed with a histrionic personality disorder. However, not all such patients have a dramatic flair, and many are withdrawn and bland. Consideration of the patient's chaotic lifestyle, history of disturbed interpersonal relationships, identity crisis, substance abuse, self-damaging acts, and manipulative tactics may lead to the diagnosis of borderline personality disorder.

We should distinguish factitious disorders from malingering. Malingerers have a manifest, recognizable environmental goal in producing signs and symptoms. They may seek hospitalization to secure financial compensation, evade the police, avoid work, or merely obtain free bed and board for the night, but they always have some apparent end for their behavior. Moreover, these patients can usually stop producing their signs and symptoms when the symptoms are no longer useful to them or when the risk becomes too high.

COMORBIDITY

Somatic Symptom Disorder

Individuals with somatic symptom disorders often have co-occurring anxiety disorders and depressive disorders, as well as comorbid medical illnesses. It is possible to have a diagnosed medical condition and receive a co-occurring diagnosis of somatic symptom disorder when the individual experiences more considerable distress and anxiety about the illness than would be expected.

Illness Anxiety Disorder

Given that illness anxiety disorder is new to DSM-5, there is limited data on comorbidity. However, a 2017 study demonstrated comorbidity of illness anxiety disorder and both depressive and anxiety disorders, especially generalized anxiety disorder and panic disorder.

Conversion Disorder (Functional Neurologic Symptom Disorder)

Medical and, especially, neurologic disorders, frequently occur among patients with conversion disorders. What one typically sees in these comorbid neurologic or medical conditions is an elaboration of symptoms stemming from the original lesion.

Depressive disorders, anxiety disorders, and somatic symptom disorder

often occur alongside conversion disorder. It is rarer with schizophrenia, however, it does occur. Personality disorders also frequently accompany conversion disorder, especially histrionic, dependent, and antisocial personality disorders, or individuals with passive–aggressive personality styling. Conversion disorders can occur, however, in persons with no predisposing medical, neurologic, or psychiatric disorder.

Psychological Factors Affecting Other Medical Conditions

All individuals with this diagnosis have at least one other medical condition that is comorbid, as per the DSM-5 diagnostic criteria.

Factitious Disorder

Many persons diagnosed with factitious disorder have comorbid psychiatric diagnoses (e.g., mood disorders, personality disorders, or substance-related disorders).

COURSE AND PROGNOSIS

Somatic Symptom Disorder

The course of the disorder is usually episodic; the episodes last from months to years with equally long quiescent periods. There may be an apparent association between exacerbations of somatic symptoms and psychosocial stressors. Although no well-conducted extensive outcome studies exist, an estimated one-third to one-half of all patients with somatic symptom disorder eventually improve significantly. A good prognosis is associated with high socioeconomic status, treatment-responsive anxiety or depression, sudden onset of symptoms, the absence of a personality disorder, the absence of childhood adversity, and the absence of a related nonpsychiatric medical condition. Most children with the disorder will recover by late adolescence or early adulthood.

Illness Anxiety Disorder

Because the disorder is a new diagnosis, there are no reliable data about the prognosis. One may extrapolate from the course of somatic symptom

disorder, which is usually episodic; the episodes last from months to years and have equally long quiescent periods in between. A good prognosis is associated with high socioeconomic status, treatment-responsive anxiety or depression, sudden onset of symptoms, the absence of a personality disorder, and the absence of a related nonpsychiatric medical condition.

Conversion Disorder (Functional Neurologic Symptom Disorder)

The onset of conversion disorder is usually acute, but a crescendo of symptomatology may also occur. Symptoms or deficits are usually of short duration, and approximately 95 percent of acute cases remit spontaneously, usually within 2 weeks in hospitalized patients. If symptoms have been present for 6 months or longer, the prognosis for symptom resolution is less than 50 percent and diminishes further, the longer that conversion is present. Recurrence occurs in one-fifth to one-fourth of people within 1 year of the first episode. Thus, one episode is a predictor for future episodes. Acute onset, presence of clearly identifiable stressors at the time of onset, a short interval between onset and the institution of treatment, and above-average intelligence are all good prognostic indicators. Paralysis, aphonia, and blindness are associated with a good prognosis, whereas tremor and seizures are poor prognostic factors.

Psychological Factors Affecting Other Medical Conditions

This condition can occur at any age. Little has been reported about course and prognosis.

Factitious Disorder

Factitious disorders typically begin in early adulthood, although they can appear during childhood or adolescence. The onset of the disorder or of discrete episodes of seeking treatment may follow a real illness, loss, rejection, or abandonment. Usually, the patient or a close relative had a hospitalization in childhood or early adolescence for genuine physical illness. After that, a long pattern of successive hospitalizations begins insidiously and evolves. As the disorder progresses, the patient becomes knowledgeable about medicine and hospitals.

Factitious disorders are incapacitating to the patient and often produce

severe trauma or untoward reactions related to treatment. A course of repeated or long-term hospitalization is incompatible with meaningful vocational work and sustaining interpersonal relationships. The prognosis, in most cases, is poor.

TREATMENT OF SOMATIC SYMPTOM AND RELATED DISORDERS

Treatment Approach

Reviews of controlled studies have shown a good efficacy of psychotherapy, particularly of the cognitive-behavioral therapy (CBT) type, and some evidence for the efficacy of pharmacotherapy in the treatment of several somatic syndromes. Kroenke and colleagues found 34 randomized controlled trials on somatoform disorders, which included more than 1,000 patients. Of these, 13 were CBT trials, 5 were antidepressant trials, and 16 involved other modalities. Overall, CBT showed the highest efficacy, with virtually all reported studies showing a significant effect of CBT on symptoms compared to no treatment. Antidepressants seem to work in painful syndromes, and the data favored older antidepressants (tricyclics) over newer ones (serotonin reuptake inhibitors [SSRIs]). Other interventions, including the use of a psychiatric consultation letter, brief psychodynamic psychotherapy, exercise, and more recently, biofeedback, have also shown beneficial effects on some of these symptoms. A more recent article reviewed 15 randomized controlled trials of the efficacy of CBT in somatoform disorders and found that CBT improved somatic, anxiety, and depressive symptoms and improved social functioning.

However, patients with somatic symptom and related disorders sometimes are not open to psychological explanations of their symptoms or psychological or psychiatric treatment. More specific treatment guidelines are listed for each diagnosis, below.

Somatic Symptom Disorder

Therapeutic goals should be modest at first and limited to small, attainable gains such as a decrease in medical visits, a commitment to a single primary care physician, and the avoidance of unnecessary tests and procedures. The

physician should prepare for a long-term commitment to the patient. Physicians should limit specialist consultations unless there is evidence of comorbid physical conditions. Some of the elements of CBT, such as diary keeping, should be incorporated into the primary care physician's treatment strategy. Recommendations for exercise, yoga, relaxation, meditation, and massage may be useful and are generally better accepted by patients than psychological treatments.

The use of a brief "consultation letter" intended for primary care physicians has demonstrated effectiveness in improving patients' functional capacity and decreasing their utilization of health services. This consultation letter provides physicians with "do's and don'ts" regarding their encounters with patients with multiple medically unexplained physical symptoms and briefly instructs them on using of a few fundamental management techniques. The letter should urge the physicians to see these patients during regularly scheduled appointments, perform brief physical examinations focusing on the area of discomfort at each visit, avoid unnecessary diagnostic procedures, invasive treatments, and hospitalizations, avoid using statements such as "symptoms are all in your head," and briefly allow/encourage patients to talk about "stressors."

A body of research has demonstrated the efficacy of CBT for the treatment of somatic symptom disorder and related syndromes. CBT-type interventions appear to help patients by modifying thoughts and behaviors associated with somatization. In the typical CBT program, the therapist systematically introduces patients to several behavioral techniques, which include relaxation training and graded increases in activities. From a cognitive perspective, CBT helps patients to identify thoughts that contribute to increased stress, inactivity, and health concern. Often, patients with this condition tend to think catastrophically about their physical symptoms. Such thoughts lead them to conclude that they are sick and must limit physical activity, creating a cycle that perpetuates the somatic process. Reports indicate that brief psychodynamic therapy of unexplained somatic symptoms may be useful, although most of the recent evidence in terms of randomized controlled trials involves CBT.

In general, we should avoid medications when treating patients with somatic symptom disorder except in the presence of clearly delineated anxious, depressive, or psychotic symptoms. Despite the development of new

pharmacologic agents such as dual (norepinephrine and serotonin) reuptake inhibitors and limited data on gabapentin, there is no evidence that a purely pharmacologic approach targeting the treatment of somatic symptom disorder will be sufficient.

Illness Anxiety Disorder

Various group and individual therapies, including CBT and psychodynamic therapy, have been proposed over the years to manage patients with health anxiety. Several controlled trials have demonstrated efficacy for CBT interventions, making CBT the prototype, first-line treatment for illness anxiety disorder. Other types of therapy, including mindfulness training, exposure therapy, and acceptance and commitment therapy, have also demonstrated some efficacy.

Limited data exist to guide pharmacologic treatment of illness anxiety disorder. There have been a few randomized, placebo-controlled trials that demonstrated benefit with SSRIs. Most reports have been anecdotal, single-blind studies. A recent randomized controlled trial of 195 patients with hypochondriasis demonstrated the efficacy and safety of fluoxetine in this patient population. Interestingly, the addition of CBT to fluoxetine conferred a slight added benefit.

Conversion Disorder (Functional Neurologic Symptom Disorder)

Many conversion syndromes have an acute, benign course and may remit spontaneously with understanding and support. Early intervention can forestall potential chronicity and the progression into a well-entrenched somatization disorder. Once chronicity has developed, intensive treatment may use all treatment modalities, including hospitalization, individual or group therapy, insight-oriented therapies, behavioral techniques, hypnosis, sodium amytal interview, physical therapy, biofeedback, relaxation training, and medication (primarily for comorbid anxiety, depression, or other somatoform disorders). Psychological interpretations or explanations do not work well early in the process, but reassuring patients that critical tests are normal and that symptoms will eventually improve may be helpful. Any implication to the patient that he or she is malingering is very counterproductive. Behavioral interventions should focus on improving self-

esteem, the capacity for emotional expression and assertiveness, and the ability to communicate comfortably with others. With chronic conversion, muscle contractures can occur, and physical therapy is necessary. Even in the absence of such contractures, however, many conversion patients find that physical therapy can be helpful for muscular symptoms or balance problems. The process of slowly progressive exercises and activity can help restore functioning.

Psychological Factors Affecting Other Medical Conditions

Treatment frequently involves communication with the patient's primary medical team as well as family. The psychoeducational intervention clarifies the role that emotional and behavioral factors play in aggravating the underlying medical condition. Medication to treat another underlying psychiatric disorder may be necessary.

Factitious Disorder

No specific psychiatric therapy has been effective in treating factitious disorders. It is a clinical paradox that patients with the disorders simulate severe illness and seek and submit to unnecessary treatment while they deny to themselves and others their actual illness and thus avoid possible treatment for it. Ultimately, the patients elude meaningful therapy by abruptly leaving the hospital or failing to keep follow-up appointments.

Treatment, thus, is best focused on management rather than on cure. Table 12-10 lists the guidelines for treating and managing factitious disorder. The three primary goals in the treatment and management of factitious disorders are (1) to reduce the risk of morbidity and mortality, (2) to address the underlying emotional needs or psychiatric diagnosis underlying factitious illness behavior, and (3) to be mindful of legal and ethical issues. Perhaps the single most crucial factor in successful management is a physician's early recognition of the disorder. In this way, physicians can forestall a multitude of painful and potentially dangerous diagnostic procedures for these patients. There must be a good liaison between psychiatrists and the medical or surgical staff. Although a few cases of individual psychotherapy exist in the literature, no consensus exists about the best approach. In general, working in concert with the patient's primary care physician is more effective than

working with the patient in isolation.

Table 12-10
Guidelines for Management and Treatment of Factitious Disorder

Keep in mind that active pursuit of a prompt diagnosis can minimize the risk of morbidity and mortality.

Minimize harm. Avoid unnecessary tests and procedures, especially if they are invasive. Treat according to clinical judgment, keeping in mind that subjective complaints may be deceptive.

Arrange regular interdisciplinary meetings to reduce conflict and splitting among staff. Manage staff countertransference.

Steer the patient toward psychiatric treatment in an empathic, nonconfrontational, face-saving manner. Avoid aggressive direct confrontation.

Treat underlying psychiatric disturbances. In psychotherapy, address coping strategies and emotional conflicts.

Appoint a primary care provider as a gatekeeper for all medical and psychiatric treatment.

Consider involving risk management and bioethicists from an early point.

Consider appointing a guardian for medical and psychiatric decisions.

As a behavioral disincentive, consider prosecution for fraud.

Table 12-11
Pediatric Factitious Disorder Imposed on Another—Basic Principles of Management

Make sure the child is safe.

Make sure the child's future safety is also assured.

Allow treatment to occur in the least restrictive setting possible.

A pediatrician should serve as "gatekeeper" for medical care utilization.

All other physicians should coordinate care with the gatekeeper.

Child-protective services should be informed whenever a child is harmed.

Family psychotherapy and/or individual psychotherapy should be instituted for the perpetrating parent and the child.

Health insurance companies, school officials, and other nonmedical sources should be asked to report possible medical abuse to the physician gatekeeper. Permission of a parent or of child-protective services must first be obtained.

The possibility should be considered of admitting the child to an inpatient or partial hospital setting to facilitate diagnostic monitoring of symptoms and to institute a treatment plan.

The child may require placement in another family. The perpetrating parent may need to be removed from the child through criminal prosecution and incarceration.

The personal reactions of physicians and staff members are of great significance in treating and establishing a working alliance with these patients, who invariably evoke feelings of futility, bewilderment, betrayal, hostility, and even contempt. In essence, staff members must abandon a fundamental element of their relationship with patients—accepting the truthfulness of the patients' statements. One appropriate psychiatric intervention is to suggest to the staff ways of remaining aware that even though the patient's illness is factitious, the patient is ill. Physicians should try not to feel resentment when patients humiliate their diagnostic prowess, and they should avoid any unmasking ceremony that sets up the patients as adversaries and precipitates their flight from the hospital. The staff should not

perform unnecessary procedures or discharge patients abruptly, both of which are manifestations of anger.

In cases of factitious disorder imposed on another, physicians have obtained a legal intervention in several instances, particularly with children. The senselessness of the disorder and the denial of false action by parents are obstacles to successful court action and often make conclusive proof unobtainable. In such cases, the treatment team should notify the child welfare and make arrangements for ongoing monitoring of the children's health (see Table 12-11 for interventions for pediatric factitious disorder imposed on another).

EPIDEMIOLOGY

Somatic Symptom Disorder

The prevalence of somatic symptom disorder is not yet known. Data do exist, however, for somatization disorder as defined by DSM-IV. Studies in the United States, Puerto Rico, Germany, and Italy found lifetime prevalence rates of "full" somatization disorder ranging from 0.1 percent in the United States to 0.8 percent in Germany. In contrast, lifetime rates of "abridged" somatization disorder ranged from 5.6 percent in Germany to 19 percent in Puerto Rico. Much higher prevalence rates have been reported for more broadly defined somatic symptom clusters.

Illness Anxiety Disorder

The prevalence of this disorder is unknown, aside from using data that relate to hypochondriasis, which gives a prevalence of 4 to 6 percent in a general medical clinic population. In other surveys, up to 10 percent of persons in the general population worry about becoming sick and incapacitated as a result.

Conversion Disorder (Functional Neurologic Symptom Disorder)

The epidemiologic information on conversion disorder is limited. Estimates vary broadly: Less than 1 percent in the general population, 5 to 14 percent among general hospital medical/surgical referrals to psychiatry consultation services, and 5 to 25 percent in treated psychiatric outpatients. The disorder appears to be more frequent in females and can occur in children as young as

7 or 8 years old. It is rare after the age of 35 years.

Psychological Factors Affecting Other Medical Conditions

The prevalence of this condition is unknown. In mental health systems, it is most frequently diagnosed in consultation–liaison psychiatry settings.

Factitious Disorder

No comprehensive epidemiologic data on factitious disorder exist. However, it is estimated to comprise approximately 1 percent of the healthcare-seeking population. Factitious disorder imposed on another account for less than 0.04 percent of reported child abuse in the United States each year.

ETIOLOGY

Somatic Symptom Disorder

Early family studies suggested an association between hysteria/Briquet syndrome in females and antisocial personality in their male first-degree relatives. Also, studies of adopted-away children highlighted the presence of alcoholism and violence in biologic fathers of women with somatization disorder. However, since developing the new diagnostic criteria, there have been no major epidemiologic studies.

Some have postulated that persons with this disorder augment and amplify their somatic sensations; they have low thresholds for and low tolerance of physical discomfort. For example, what persons usually perceive as abdominal pressure, persons with somatic symptom disorder experience as abdominal pain. They may focus on bodily sensations, misinterpret them, and become alarmed by them because of a faulty cognitive scheme.

Others have proposed a social learning model. They see the symptoms of this disorder as a request for admission to the sick role made by a person facing seemingly insurmountable and unsolvable problems. The sick role offers an escape that allows a patient to avoid noxious obligations, to postpone unwelcome challenges, and to evade usual duties and obligations.

Illness Anxiety Disorder

The etiology is unknown. The social learning model described for somatic symptom disorder may apply to this disorder as well, with a similar dynamic to what we described above.

Conversion Disorder (Functional Neurologic Symptom Disorder)

Biologic Factors. The neuropsychologic conceptualization speaks of an inherent deficit in certain brain functions, especially those in the dominant hemisphere that may interfere with verbal associations. Also, functional MRI studies have shown differences in brain activation between patients with conversion disorder and controls.

Psychological Factors The behavioral theory attributes conversion disorder to faulty childhood learning, with the nonadaptive behavioral responses used for secondary gain and control of interpersonal relationships. The psychoanalytic theory, on the other hand, describes symptoms as compromise formations with primary gain of conflict resolution through a partial expression of the conflict without conscious awareness of its significance. Some have suggested a strong relationship between childhood traumatization by sexual or physical abuse and a later propensity for conversion disorder. Other studies, however, do not confirm such an association.

Factitious Disorder

Etiology is generally not clear, except that a common denominator is that these patients tend to be avid medical service seekers. The underlying motivations for the behaviors are likely unconscious. Two factors may underlie most cases of factitious disorder: (1) an affinity for the medical system, and (2) poor, maladaptive coping skills. In the case of factitious disorder imposed on another, psychodynamic theories predominately view the disorder as an objectification of the child to serve the parent's psychological needs.

Feeding and Eating Disorders

This chapter deals with several feeding and eating disorders, including anorexia nervosa, bulimia nervosa, binge-eating disorder, and other specified feeding and eating disorders. There are different feeding and eating disorders that are typically associated with childhood and adolescence (e.g., pica, rumination disorder, and avoidant/restrictive food intake disorder); Neurodevelopmental Disorders and Other Childhood Disorders (Chapter 2) covers those disorders.

CLINICAL FEATURES

Anorexia Nervosa

The term anorexia nervosa comes from the Greek term for "loss of appetite" and a Latin word implying nervous origin. Anorexia nervosa is a syndrome characterized by three essential criteria, one behavioral, one psychopathological, and the last, physiologic. The first is self-induced starvation, to a significant degree (behavioral). The second is a relentless drive for thinness or a morbid fear of fatness (psychopathological). The third criterion is the presence of medical signs and symptoms resulting from starvation (physiologic). Anorexia nervosa is often, but not always, associated with disturbances of body image, the perception that one is distressingly large despite evident medical starvation. The distortion of body image is disturbing when present; it is, however, not pathognomonic, invariable, or required for diagnosis. Two subtypes of anorexia nervosa exist: restricting and binge/purge. The theme in all anorexia nervosa subtypes is the highly disproportionate emphasis placed on thinness as a vital source of self-esteem, with weight, and to a lesser degree, shape, becoming the overriding

and consuming daylong preoccupation of thoughts, mood, and behaviors.

Approximately half of anorexic persons will lose weight by drastically reducing their total food intake. The other half of these patients will not only diet but will also regularly engage in binge eating, followed by purging behaviors. Some patients routinely purge after eating small amounts of food. Anorexia nervosa is much more prevalent in females than in males and usually has its onset in adolescence. Hypotheses of an underlying psychological disturbance in young women with the disorder include conflicts surrounding the transition from girlhood to womanhood. Some have also suggested that psychological issues related to feelings of helplessness and difficulty establishing autonomy also contribute to the development of the disorder. Bulimic symptoms can occur as a separate disorder or as part of anorexia nervosa. Persons with either disorder are excessively preoccupied with weight, food, and body shape. The outcome of anorexia nervosa varies from spontaneous recovery to a waxing and waning course to death.

Bulimia Nervosa

People with bulimia nervosa have episodes of binge eating combined with inappropriate ways of stopping weight gain. Physical discomfort—for example, abdominal pain or nausea—terminates the binge eating, which is often followed by feelings of guilt, depression, or self-disgust. Unlike patients with anorexia nervosa, those with bulimia nervosa typically maintain average body weight.

The term bulimia nervosa derives from the terms for "ox-hunger" in Greek and "nervous involvement" in Latin. For some patients, bulimia nervosa may represent a failed attempt at anorexia nervosa, sharing the goal of becoming very thin, but occurring in an individual less able to sustain prolonged semistarvation or severe hunger as consistently as classic restricting anorexia nervosa patients. For others, eating binges represent "breakthrough eating" episodes of giving in to hunger pangs generated by efforts to limit eating to maintain a socially desirable level of thinness. Still, others use binge eating as a means to self-medicate during times of emotional distress. Regardless of the reason, eating binges provoke panic as individuals feel that their eating has been out of control. The unwanted binges lead to subsequent attempts to avoid the feared weight gain by a variety of compensatory behaviors, such as

purging or excessive exercise.

Binge-Eating Disorder

Individuals with binge-eating disorder engage in recurrent binge eating during which they eat an abnormally large amount of food over a short time. Unlike bulimia nervosa, patients with binge-eating disorder do not compensate in any way after a binge episode (e.g., vomiting, laxative use). Binge episodes often occur in private, generally include foods of dense caloric content, and, during the binge, the person feels he or she cannot control his or her eating.

Other Specified Feeding or Eating Disorders

This diagnostic category also includes eating conditions that may cause significant distress but do not meet the full criteria for a classified eating disorder. Conditions included in this category include night-eating syndrome, purging disorder, and subthreshold forms of anorexia nervosa, bulimia nervosa, and binge-eating disorder.

Night-Eating Syndrome. Night-eating syndrome is characterized by the consumption of large amounts of food after the evening meal. Individuals generally have little appetite during the day and suffer from insomnia.

Purging Disorder. Purging disorder is characterized by recurrent purging behavior after consuming a small amount of food in persons of average weight who have a distorted view of their weight or body image. Purging behavior includes self-induced vomiting, laxative abuse, enemas, and diuretics. This behavior should not be associated with anorexia nervosa. Purging disorder is differentiated from bulimia nervosa because purging behavior occurs after eating small quantities of food or drink and does not occur as a result of a binge episode.

DIAGNOSIS AND CLINICAL FEATURES

Anorexia Nervosa

The onset of anorexia nervosa usually occurs between the ages of 10 and 30

years. We summarize the diagnostic criteria in DSM-5 and ICD-10 for the disorder in Table 13-1.

Intense fear of gaining weight and becoming obese is present in all patients with the disorder and undoubtedly contributes to their lack of interest in and even resistance to therapy. Most aberrant behavior directed toward losing weight occurs in secret. Patients with anorexia nervosa usually refuse to eat with their families or in public places. They lose weight by drastically reducing their total food intake, with a disproportionate decrease in high-carbohydrate and fatty foods.

The term anorexia is a misnomer because the loss of appetite is usually rare until late in the disorder. Evidence that patients are frequently thinking about food is their passion for collecting recipes and for preparing elaborate meals for others. Some patients cannot continuously control their voluntary restriction of food intake, and so have eating binges. These binges usually occur secretly, often at night, and are frequently followed by self-induced vomiting. Patients abuse laxatives and even diuretics to lose weight, and ritualistic exercising, extensive cycling, walking, jogging, and running are everyday activities.

Patients with the disorder show peculiar behavior surrounding food. They hide food all over the house and frequently carry large quantities of candies in their pockets and purses. While eating meals, they try to dispose of food in their napkins or hide it in their pockets. They cut their meat into tiny pieces and spend a great deal of time rearranging these pieces on their plates. If someone confronts the patient about the behavior, they often deny that it is unusual or flatly refuse to discuss it.

Obsessive-compulsive behavior, depression, and anxiety are other psychiatric symptoms of anorexia nervosa most frequently noted clinically. Patients tend to be rigid and perfectionist, and somatic complaints, especially epigastric discomfort, are usual. Compulsive stealing, usually of candies and laxatives but occasionally of clothes and other items, may occur.

Patients with the disorder frequently have poor sexual adjustment. Many adolescent patients with anorexia nervosa have delayed psychosocial sexual development; in adults, a markedly decreased interest in sex often accompanies the onset of the disorder. A minority of anorexic patients have a premorbid history of promiscuity, substance abuse, or both, but during the disorder show a decreased interest in sex.

Patients usually come to medical attention when their weight loss becomes apparent. As the weight loss grows profound, physical signs such as hypothermia (as low as 35°C), dependent edema, bradycardia, hypotension, and lanugo (the appearance of neonatal-like hair) appear, and patients show a variety of metabolic changes. These and other medical complications are listed in Table 13-2.

Table 13-1
Anorexia Nervosa Diagnoses

| Disorder | Anorexia Nervosa | |
	DSM-5	ICD-10
Diagnostic name	Anorexia nervosa	Anorexia nervosa

Symptom	• Food restriction leading to abnormally low weight
	• Fear of gaining weight and behaviors to prevent weight gain
	• Distorted body image
	  • Misperceiving weight or shape
	  • Self-evaluation based on thinness, lack of recognition of the seriousness of one's weight
		• Deliberate weight loss induced by the patient
		• Fear of being fat or flabby
		• Associated physiologic disturbances due to low weight
		• Specific behaviors:
		  • Restricted diet
		  • Excess exercise
		  • Binging behavior
		  • Use of appetite suppressants and diuretics

Required number of	All	

	symptom	
Exclusions		Loss of appetite (physical or psychological)
Symptom specifiers	Restricting type: Primary behaviors are dieting, fasting, and exercise for last 3 mo Binge eating type: Binging and purging behavior for last 3 mo. Can include use of laxatives or other substances to aid purging	
Course specifiers	Partial remission: Symptoms present but no longer an abnormally low weight Full remission: No symptoms for a sustained period	
Severity specifiers	Severity is measured by BMI level See DSM-5 for ranges	
Comments		If lacking core symptoms, the diagnosis of "atypical anorexia nervosa" is made

Table 13-2
Medical Complications of the Eating Disorders

Disorder and System	Consequence

Affected	
Anorexia Nervosa	
Vital signs	Bradycardia, hypotension with marked orthostatic changes, hypothermia, poikilothermia
General	Muscle atrophy, loss of body fat
Central nervous system	Generalized brain atrophy with enlarged ventricles, decreased cortical mass, seizures, abnormal electroencephalogram
Cardiovascular	Peripheral (starvation) edema, decreased cardiac diameter, narrowed left ventricular wall, decreased response to exercise demand, superior mesenteric artery syndrome
Renal	Prerenal azotemia
Hematologic	Anemia of starvation, leukopenia, hypocellular bone marrow
Gastrointestinal	Delayed gastric emptying, gastric dilatation, decreased intestinal lipase and lactase
Metabolic	Hypercholesterolemia, nonsymptomatic hypoglycemia, elevated liver enzymes, decreased bone mineral density
Endocrine	Low luteinizing hormone, low follicle-stimulating hormone, low estrogen or testosterone, low/normal thyroxine, low triiodothyronine, increased reverse triiodothyronine, elevated cortisol, elevated growth hormone, partial diabetes insipidus, increased prolactin
Bulimia Nervosa and Binge Eating and Purging Type Anorexia Nervosa	
Metabolic	Hypokalemic alkalosis or acidosis, hypochloremia, dehydration

Renal	Prerenal azotemia, acute and chronic renal failure
Cardiovascular	Arrhythmias, myocardial toxicity from emetine (ipecac)
Dental	Lingual surface enamel loss, multiple caries
Gastrointestinal	Swollen parotid glands, elevated serum amylase levels, gastric distention, irritable bowel syndrome, melanosis coli from laxative abuse
Musculoskeletal	Cramps, tetany

Subtypes. Anorexia nervosa has two clinical subtypes: food restricting and purging. In the food-restricting category, present in approximately 50 percent of cases, food intake is highly restricted (usually with attempts to consume fewer than 300 to 500 calories per day and no fat grams) and the patient may be relentlessly and compulsively overactive, with overuse athletic injuries. In the purging subtype, patients alternate attempts at rigorous dieting with intermittent binge or purge episodes. Purging represents a secondary compensation for the unwanted calories, most often accomplished by self-induced vomiting, frequently by laxative abuse, less frequently by diuretics, and occasionally with emetics. Sometimes, repetitive purging occurs without prior binge eating, after ingesting only relatively few calories. Both types may be socially isolated and have depressive disorder symptoms and diminished sexual interest. Overexercising and perfectionistic traits are also common in both types.

Those who practice binge eating and purging share many features with persons who have bulimia nervosa without anorexia nervosa. Those who binge eat and purge tend to have families in which some members are obese, and they have histories of heavier body weights before the disorder than do persons with the restricting type. Binge eating–purging persons are likely to be associated with substance abuse, impulse control disorders, and personality disorders. Persons with restricting anorexia nervosa often have obsessive-compulsive traits concerning food and other matters. Some persons with anorexia nervosa may purge but not binge.

Patients with anorexia nervosa are often secretive, deny their symptoms,

and resist treatment. In almost all cases, relatives or intimate acquaintances must confirm a patient's history. The mental status examination usually shows a patient who is alert and knowledgeable on the subject of nutrition and who is preoccupied with food and weight.

A young woman who weighed 10 percent above the average weight but was otherwise healthy, functioning well, and working hard as a university student joined a track team. She started training for hours a day, more than her teammates, began to perceive herself as fat, and thought that her performance would be enhanced if she lost weight. She started to diet and reduced her weight to 87 percent of the "ideal weight" for her age according to standard tables. At her point of maximum weight loss, her performance declined, and she pushed herself even harder in her training regimen. She started to feel apathetic and morbidly afraid of becoming fat. Her food intake became restricted, and she stopped eating anything containing fat. Her menstrual periods became skimpy and infrequent but did not cease. (Courtesy of Arnold E. Andersen, M.D. and Joel Yager, M.D.)

Bulimia Nervosa

People with bulimia nervosa have binge episodes with compensatory behaviors. Like persons with anorexia nervosa, they fear becoming fat; however, they are not severely thin. We summarize the diagnostic criteria in DSM-5 and ICD-10 for the disorder in Table 13-3.

Table 13-3
Bulimia Nervosa Diagnoses

	Bulimia Nervosa	
Disorder	DSM-5	ICD-10
Diagnostic name	Bulimia nervosa	Bulimia nervosa
Duration	Occurs at least once a week for	

	3 mo	

Symptom	1. Repeated binge-eating episodes
	  • Occurring within 2 hr period
	  • Loss of control during the episode
	2. Compensatory behaviors to prevent weight gain, such as
	  • Vomiting
	  • Laxatives
	  • Diuretics, other substances
	  • Excessive exercise
	  • Fasting
	3. Self-evaluation based on weight and shape
		• Binging
		• Preoccupation with weight control
		• Preoccupation with body shape and weight
		• Associated physiologic disturbances due to repeated vomiting
		• Specific compensatory behaviors:
		  • Vomiting
		  • Use of purgatives

Required number of symptom	All 3	Not specified
Exclusions	Does not occur only during episodes of anorexia nervosa	
Course specifiers	Partial remission: Full symptoms no longer met for a sustained time Full remission: No symptoms for a sustained period	
Severity specifiers	Severity is measured by the average number of compensatory behaviors in	

When making a diagnosis of bulimia nervosa, clinicians should explore the possibility that the patient has experienced a brief or prolonged prior bout of anorexia nervosa, which is present in approximately half of those with bulimia nervosa. The binging behavior commonly precedes vomiting by about 1 year.

Vomiting is frequent and is often induced by sticking a finger down the throat. Some patients can vomit at will. Vomiting decreases the abdominal pain and the feeling of being bloated and allows patients to continue eating without fear of gaining weight. The acid content of vomitus can damage tooth enamel, a not uncommon finding in patients with the disorder. Depression, sometimes called postbinge anguish, often follows the episode. During binges, patients eat food that is sweet, high in calories, and generally soft or smooth textured, such as cakes and pastry. Some patients prefer bulky foods without regard to taste. The food is eaten secretly and rapidly and is sometimes not even chewed.

Jean was a 25-year-old woman admitted to an inpatient unit after a superficial suicide attempt. During her initial evaluation, she revealed that she had struggled with bulimia nervosa since her early teens. She said that she has always tended "to be on the heavy side" and would respond by skipping meals during the day, only to binge on "junk food" in the evening. Her binge eating occurred almost daily, and at least two or three times a week, Jean would force herself to vomit afterward. She also used daily laxatives and ran for at least an hour a day. Despite these behaviors, she could not lose weight, which distressed her to the point that she cut her wrists, although Jean admitted she had really "only scratched myself." She drank socially and did not use illicit drugs. On examination, she appeared somewhat overweight with a BMI of 29. Her dentition showed signs of enamel erosion, and she had calluses on her fingers from her induced vomiting. There were superficial scratches on her wrist from when she cut herself. She had normal electrolytes on

laboratory evaluation.

Jean had a high school education and had been married for 2 years, and she described her marriage as "rocky" as her husband frequently traveled on business. She said she rarely saw her parents, who were "always criticizing me." She did not work and said she was bored most of the time. On several occasions, while her husband was away, she would meet up with former boyfriends and sometimes slept with them. She felt that her guilt over these affairs contributed to her depression and suicidal ideation.

During her hospital stay, she had nutritional counseling and ate regularly scheduled meals, for which she had to be observed. After meals, she could use the bathroom but was instructed not to flush the toilet. This continued for 2 days until a staff member found a plastic bag of partially digested food in a trash can, after which the staff would observe her for an hour after meals. Initially, she would use a hospital courtyard for jogging, and when that was restricted, the evening staff observed her doing calisthenics in her room. Several staff members also saw her flirting with the male patients, and her therapist reminded her of the unit rules regarding patient relationships. Her treatment consisted of a behavioral schedule and frequent observation while her therapy focused on her difficulties with self-esteem and interpersonal interactions. Her psychiatrist initiated fluoxetine, 20 mg. Her purging behaviors decreased over the next 2 weeks to the point where she was considered appropriate for outpatient treatment.

Most patients with bulimia nervosa are within their normal weight range, but some may be underweight or overweight. These patients are concerned about their body image and their appearance, worried about how others see them, and concerned about their sexual attractiveness. Most are sexually active, compared with anorexia nervosa patients, who are not interested in sex. They may have a history of pica and struggles during meals.

Table 13-4
Binge-Eating Disorder

	Binge-Eating Disorder	
Disorder	**DSM-5**	**ICD-10**
Diagnostic name	Binge-eating disorder	Bulimia nervosa, nonpurging type
Duration	Occurs at least once a week for 3 mo	

Symptom	• Repeated binge-eating episodes
	  • Occurring within 2 hr period
	  • Loss of control during the episode
	• Binge-associated behaviors or reactions
	  • Eating quicker than normal
	  • Eating until uncomfortably full
	  • Eating despite not being hungry
	  • Eating alone to avoid embarrassment
	  • Feeling guilty or disgusted after eating
		Similar to ICD-10 bulimia nervosa minus the specific compensatory behaviors

Required number of symptom	Binge behaviors plus at least three of the associated behaviors or reactions	
Psychosocial consequences of symptoms	Marked distress	

Exclusions	No compensatory behavior as in bulimia nervosa
Course specifiers	Partial remission: Occurrences are less frequent (<1 episode/wk) Full remission: No symptoms for a sustained period
Severity specifiers	Severity is measured by the average number of compensatory behaviors in a weeks' time See DSM-5 for ranges

Binge-Eating Disorder

Individuals with binge-eating disorder engage in frequent binges, often independent of feeling hungry. We summarize the diagnostic criteria in DSM-5 and ICD-10 for the disorder in Table 13-4.

Other Specified Feeding and Eating Disorder

Night-Eating Syndrome. As implied by the name, night-eating syndrome includes recurrent episodes of hyperphagia or night eating. It may be associated with insomnia and a lack of desire for food in the morning.

Patients with night-eating syndrome usually consume a large portion of their daily calorie intake after the evening meal. They may also wake up during the night and eat upon awakening. Some patients believe that they can only sleep if they eat. Depressed mood is common among these patients, especially during the evening and night hours.

PATHOLOGY AND LABORATORY EXAMINATION

Anorexia Nervosa

A patient with anorexia nervosa must have a thorough general physical and neurologic examination. If the patient is vomiting, a hypokalemic alkalosis may be present. Because most patients are dehydrated, serum electrolyte levels must be determined initially and periodically. Hospitalization may be necessary to deal with medical complications.

A complete blood count often reveals leukopenia with a relative lymphocytosis in emaciated patients with anorexia nervosa. If binge eating and purging are present, serum electrolyte determination reveals hypokalemic alkalosis. Fasting serum glucose concentrations are often low during the emaciated phase, and serum salivary amylase concentrations may increase if the patient is vomiting.

Electrocardiographic (ECG) changes, such as T-wave flattening or inversion, ST segment depression, and lengthening of the QT interval, have been noted in the emaciated stage of anorexia nervosa. The ST segment and T-wave changes are usually secondary to electrolyte disturbances; emaciated patients have hypotension and bradycardia. ECG changes may also result from potassium loss, which can lead to death. Young girls may have a high serum cholesterol level. All these values revert to normal with nutritional rehabilitation and cessation of purging behaviors. Endocrine changes related to being underweight may occur. These can include amenorrhea, mild hypothyroidism, and hypersecretion of corticotrophin-releasing hormone, which revert to normal with weight gain (see Table 13-2).

Bulimia Nervosa

Bulimia nervosa can result in electrolyte abnormalities and various degrees of starvation, although it may not be as apparent as in low-weight patients with anorexia nervosa. Thus, even normal-weight patients with bulimia nervosa should have laboratory studies of electrolytes and metabolism. In general, thyroid function remains intact in bulimia nervosa, but patients may show nonsuppression on a dexamethasone-suppression test. Dehydration and electrolyte disturbances are likely to occur in patients with bulimia nervosa who purge regularly. These patients commonly exhibit hypomagnesemia and hyperamylasemia. Although not a core diagnostic feature, many patients with bulimia nervosa have menstrual disturbances. Hypotension and bradycardia

occur in some patients.

DIFFERENTIAL DIAGNOSIS

Anorexia Nervosa

The differential diagnosis of anorexia nervosa is complicated, as patients often deny symptoms, are secretive about their eating habits, and resist seeking treatment. Thus, it may be difficult to identify the mechanism of weight loss and the patient's associated ruminative thoughts about distortions of body image.

We should differentiate the eating disorders from one another. Attention to specific criteria, including whether the patient is of average weight, is essential. However, the two conditions can coexist.

We must ascertain that a patient does not have a medical illness that can account for the weight loss (e.g., a brain tumor or cancer). Weight loss, peculiar eating behaviors, and vomiting can occur in several mental disorders. Depressive disorders and anorexia nervosa have several features in common, such as depressed feelings, crying spells, sleep disturbance, obsessive ruminations, and occasional suicidal thoughts. The two disorders, however, have several distinguishing features. In general, a patient with a depressive disorder has decreased appetite, whereas a patient with anorexia nervosa claims to have a normal appetite and to feel hungry; only in the severe stages of anorexia nervosa do patients have decreased appetite.

In contrast to depressive agitation, the hyperactivity seen in anorexia nervosa is planned and ritualistic. The preoccupation with recipes, the caloric content of foods, and the preparation of gourmet feasts is typical of patients with anorexia nervosa but is absent in patients with a depressive disorder. In depressive disorders, patients have no intense fear of obesity or disturbance of body image.

Weight fluctuations, vomiting, and peculiar food handling may occur in somatization disorder. On rare occasions, a patient may have both a somatization disorder and anorexia nervosa, in which case we should diagnose both. In general, patients with somatization disorder have less weight loss than patients with anorexia nervosa and do not fear weight gain. Amenorrhea for 3 months or longer is unusual in somatization disorder.

Patients with schizophrenia that include delusions about food rarely are concerned with caloric content. More likely, they believe someone poisoned the food. Patients with schizophrenia are rarely preoccupied with a fear of becoming obese and do not have the hyperactivity seen with anorexia nervosa. Patients with schizophrenia have bizarre eating habits but not the entire syndrome of anorexia nervosa.

There are rare conditions of unknown etiology in which a hyperactive vagus nerve causes changes in eating patterns that are associated with weight loss, sometimes severe. In such cases, we may see bradycardia, hypotension, and other parasympathomimetic signs and symptoms. Because the vagus nerve relates to the enteric nervous system, eating may be associated with gastric distress such as nausea or bloating. Patients do not generally lose their appetite. Treatment is symptomatic. Anticholinergic drugs can reverse hypotension and bradycardia, which may be life-threatening.

Bulimia Nervosa

We cannot make the diagnosis of bulimia nervosa if the binge-eating and purging behaviors occur exclusively during episodes of anorexia nervosa. In such cases, the diagnosis is anorexia nervosa, binge eating–purging type. Additionally, we should distinguish bulimia nervosa from binge-eating disorder, which typically includes binge-eating behaviors but no compensatory or purging behaviors.

We must ascertain that patients have no neurologic disease, such as epileptic-equivalent seizures, central nervous system tumors, Klüver–Bucy syndrome, or Kleine–Levin syndrome. Klüver–Bucy syndrome includes visual agnosia, compulsive licking and biting, an examination of objects by the mouth, inability to ignore any stimulus, placidity, altered sexual behavior (hypersexuality), and altered dietary habits, especially hyperphagia. The syndrome is exceedingly rare and is unlikely to cause a problem in the differential diagnosis. Kleine–Levin syndrome consists of periodic hypersomnia lasting for 2 to 3 weeks and hyperphagia. As in bulimia nervosa, the onset is usually during adolescence, but the syndrome is more common in men than in women.

Some patients with bulimia nervosa have multiple comorbid impulsive behaviors, including substance abuse, and lack of ability to control

themselves in such diverse areas as money management (resulting in impulse buying and compulsive shopping) and sexual relationships (often resulting in a short, passionate attachment and promiscuity). They exhibit self-mutilation, chaotic emotions, and chaotic sleeping patterns. They usually meet the criteria for borderline personality disorder and other mixed personality disorders and, not infrequently, bipolar II disorder. When bulimia nervosa co-occurs with one of these disorders, we should note both diagnoses.

Binge-Eating Disorder

Binge-eating disorder and bulimia nervosa share the same core feature of recurrent binge eating. Binge-eating disorder is distinct from bulimia nervosa, however, in that binge-eating disorder patients do not report repetitive compensatory behaviors such as vomiting, laxative abuse, or excessive dieting. Binge-eating disorder is distinct from anorexia nervosa in that patients do not exhibit an extreme drive for thinness and are of average weight or are obese.

Other Specified Feeding and Eating Disorder

Night-Eating Syndrome. Night-eating syndrome is common among patients with other eating disorders, particularly bulimia nervosa and binge-eating disorder. Although we can find night eating in patients with bulimia nervosa and binge-eating disorder, it is the characteristic sign of night-eating disorder. Also, the amount of food consumed during eating episodes is usually lower in night-eating disorder than in bulimia nervosa and binge-eating disorder. Unlike other eating disorders, patients with night eating syndrome are not overly concerned about body image and weight. Patients with night-eating syndrome are also at higher risk for obesity and metabolic syndrome.

Recurrent episodes of involuntary eating characterize a sleep-related eating disorder during the night. These episodes can lead to severe consequences such as the ingesting of nonedible foods or substances, dangerous behaviors while searching for or preparing food, and sleep-related injury. The eating episodes usually occur after the patient has gone to sleep and may occur while the patient is unconscious or asleep. The sleep-related eating disorder

also has high comorbidity with sleepwalking, restless legs syndrome, and obstructive sleep apnea, conditions that are rarely found among night-eating syndrome patients. Episodes of sleep-related eating disorder have been reported after the use of certain medications, including zolpidem, triazolam, olanzapine, and risperidone.

COMORBIDITY

Anorexia Nervosa

Table 13-5 lists comorbid psychiatric conditions associated with anorexia nervosa. Overall, anorexia nervosa is associated with depression in 50 percent of cases, social phobia in 22 percent of cases, and obsessive-compulsive disorder (OCD) in 35 percent of cases.

The suicide rate is higher in persons with the binge eating–purging type of anorexia nervosa than in those with the restricting type.

Binge eating–purging persons are likely to be associated with substance abuse, impulse control disorders, and personality disorders. Persons with restricting anorexia nervosa often have obsessive-compulsive traits concerning food and other matters. Some persons with anorexia nervosa may purge but not binge.

Bulimia Nervosa

Bulimia nervosa occurs in individuals with high rates of mood disorders and impulse control disorders. Bulimia nervosa also co-occurs with substance use disorders, particularly alcohol. Patients with bulimia nervosa also have increased rates of anxiety disorders, bipolar I disorder, dissociative disorders, and histories of sexual abuse. Patients with bulimia nervosa who have concurrent seasonal affective disorder and patterns of atypical depression (with overeating and oversleeping in low-light months) may manifest seasonal worsening of both bulimia nervosa and depressive features. Individuals with bulimia nervosa who purge may be at risk for certain medical complications such as hypokalemia from vomiting or laxative abuse and hypochloremic alkalosis. Those who vomit repeatedly are at risk for gastric and esophageal tears, although these complications are rare.

Binge-Eating Disorder

Binge-eating disorder is associated with mood, anxiety, and substance use disorders. Also, nearly half of individuals with binge-eating disorder are obese and are at risk for medical complications associated with obesity. Patients with binge-eating disorder are also more likely to have an unstable weight history with frequent episodes of weight cycling (the gaining or losing of more than 10 kg). The disorder may be associated with insomnia, early menarche, neck or shoulder and lower back pain, chronic muscle pain, and metabolic disorders.

Table 13-5
Lifetime Comorbidities of Various Psychiatric Disorders with Eating Disorders

Diagnosis	No Eating Disorder %	Anorexia Nervosa (%) %	AOR[a]	Bulimia Nervosa (%) %	AOR[a]	Binge-Eating Disorder (%) %	AOR[a]

COURSE AND PROGNOSIS

Anorexia Nervosa

The precise course of the illness varies substantially, although specific patterns have emerged in the literature. Follow-up studies of patients with anorexia nervosa reveal that, at the time of assessment, approximately 30 to 50 percent have achieved full recovery, and 10 to 20 percent remain chronically ill. The remainder improve but continue to struggle with certain disordered behaviors. The chronically ill group often requires multiple hospitalizations. Of note, anorexia nervosa has a mortality rate as high as that associated with any psychiatric illness. Compared to the general population, individuals with the illness are up to six times more likely to die. The majority of deaths are attributable to medical complications of low weight and malnourishment, but a smaller, yet significant, proportion of deaths (approximately 1 in 5) are due to suicide.

Although additional research is needed to identify predictors of outcome in anorexia nervosa, studies have found that adolescents with a shorter duration of illness tend to have a better prognosis, emphasizing the importance of early detection and intervention. Studies examining inpatients with anorexia nervosa just before and after discharge have also identified specific predictors of posttreatment outcomes. Individuals who achieve full weight-restoration on an inpatient unit and maintain their weight in the first month after discharge are, perhaps unsurprisingly, more likely to remain at a healthy weight up to a year after treatment. Lower BMI at discharge and weight loss in the first month after treatment, on the other hand, predict more unsatisfactory long-term outcomes. Additionally, individuals who demonstrate an ability to consume a diet that is high in variety and energy density (i.e., a greater concentration of kcal/g) before discharge seem to do better after treatment.

Bulimia Nervosa

Bulimia nervosa is characterized by higher rates of partial and full recovery compared with anorexia nervosa. Those receiving treatment fare much better than those who are untreated. Untreated patients tend to remain chronic or may show small, but generally unimpressive, degrees of improvement with time. Research has yet to identify any clear predictors of outcome in bulimia nervosa. Studies have examined a variety of potential prognostic factors,

including duration of illness, age of onset, illness severity, comorbid diagnoses, and personality characteristics, with mixed results. In individuals who receive treatment for bulimia nervosa, studies have found that rapid symptom reduction predicts better treatment outcomes.

Binge-Eating Disorder

We know little about the course of binge-eating disorder. Severe obesity is a long-term effect in over 3 percent of patients with the disorder. One prospective study of women in the community with binge-eating disorder suggested that by 5 years of follow-up, fewer than one-fifth of the sample still had clinically significant eating disorder symptoms.

Other Specified Feeding and Eating Disorder

Night-Eating Syndrome. The age of onset for night-eating syndrome ranges from the late teens to the late 20s and has a long-lasting course with periods of remission with treatment. Patients who experience poor sleep quality are more likely to develop diabetes, obesity, hypertension, and cardiovascular disease.

TREATMENT APPROACH

Treatment of Anorexia Nervosa

Given the complicated psychological and medical implications of anorexia nervosa, a comprehensive treatment plan, including hospitalization when necessary and both individual and family therapy, is recommended. It is important to consider behavioral, interpersonal, and cognitive approaches. In many cases, medication may also help.

Hospitalization. The first consideration in the treatment of anorexia nervosa is to restore patients' nutritional state; dehydration, starvation, and electrolyte imbalances can seriously compromise health and, in some cases, lead to death. When deciding whether to hospitalize a patient, we should consider the patient's medical condition and the amount of structure needed to ensure cooperation. In general, patients with anorexia nervosa who are 20

percent below the normal weight for their height require inpatient programs, and patients who are 30 percent below their expected weight require psychiatric hospitalization for 2 to 6 months.

Inpatient psychiatric programs for patients with anorexia nervosa generally use a combination of a behavioral management approach, individual psychotherapy, family education and therapy, and, in some cases, psychotropic medications. Staff members should maintain a firm yet supportive approach to patients, often through a combination of positive reinforcers (praise) and negative reinforcers (restriction of exercise). The program must have some flexibility for individualizing treatment to meet patients' needs and cognitive abilities. Patients must become willing participants for treatment to succeed in the long run.

Most patients are uninterested in psychiatric treatment and even resist it; they are brought to a doctor's office unwillingly by agonizing relatives or friends. The patients rarely accept the recommendation of hospitalization without arguing and criticizing the proposed program. Emphasizing the benefits, such as relief of insomnia and depressive signs and symptoms, may help persuade the patients to admit themselves willingly to the hospital. Relatives' support and confidence in the physicians and treatment team are essential for reinforcing the firm recommendations made on the unit. We should warn patients' families that the patients will resist admission and, for the first several weeks of treatment, will make many dramatic pleas for their families' support to obtain release from the hospital program. We should consider compulsory admission or commitment only when the risk of death from the complications of malnutrition is likely. On rare occasions, patients prove that the doctor's statements about the probable failure of outpatient treatment are wrong. They may gain a specified amount of weight by the time of each outpatient visit, but such behavior is uncommon, and a period of inpatient care is usually necessary.

HOSPITAL MANAGEMENT. The following considerations apply to the general management of patients with anorexia nervosa during a hospitalized treatment program. Patients should be weighed daily, early in the morning after emptying the bladder. The staff should record daily fluid intake and urine output. If vomiting is occurring, hospital staff members must monitor serum electrolyte levels regularly and watch for the development of

hypokalemia. Because patients often regurgitate food after meals, the staff may be able to control vomiting by making the bathroom inaccessible for at least 2 hours after meals or by having an attendant in the bathroom to prevent the opportunity for vomiting. Constipation in these patients is relieved when they begin to eat normally. We may occasionally use stool softeners, but never laxatives. If diarrhea occurs, it usually means that patients are surreptitiously taking laxatives. Because of the risk of refeeding syndrome when patients immediately start eating an enormous number of calories, the hospital staff should start patients on a low-caloric intake initially (e.g., 1,000 to 1,400 kcals/day), and increase slowly by approximately 400 kcals every few days. It is wise to give these calories in six equal feedings throughout the day so that patients need not eat a large amount of food at one sitting. Giving patients a liquid food supplement may be advisable, because they may be less apprehensive about gaining weight slowly with formula than by eating food. After discharging patients from the hospital, clinicians usually find it necessary to continue outpatient supervision of the problems identified in the patients and their families.

Psychotherapy

FAMILY-BASED THERAPY. Family-based therapy (FBT) is an effective treatment for anorexia nervosa, particularly in patients under the age of 18. FBT, also known as the Maudsley method, generally consists of three phases of treatment. In phase one, treatment focuses on the restoration of the patient's physical health, with decisions about what or when the patient will eat made by the parents. Once the patient has begun to gain weight and shown improvement in symptoms of anorexia nervosa, FBT moves on to phase two. In this phase, the patient gradually begins to take responsibility for decisions about eating. In phase three, the focus shifts to the patient's growth and development.

COGNITIVE-BEHAVIORAL THERAPY. Cognitive and behavioral therapy principles can be applied in both inpatient and outpatient settings and have been found effective for inducing weight gain. Monitoring is an essential component of cognitive-behavioral therapy (CBT). Therapists teach patients to monitor their food intake, their feelings and emotions, their binging and purging behaviors, and their problems in interpersonal relationships. They also teach

the patients cognitive restructuring to identify automatic thoughts and to challenge their core beliefs. Problem-solving is a specific method whereby patients learn how to think through and devise strategies to cope with their food-related and interpersonal problems. These techniques can help address a patient's vulnerability to rely on anorectic behavior as a means of coping.

DYNAMIC PSYCHOTHERAPY. We sometimes use dynamic expressive-supportive psychotherapy in the treatment of patients with anorexia nervosa, but their resistance may make the process difficult and painstaking. Because patients view their symptoms as constituting the core of their specialness, therapists must avoid excessive investment in trying to change their eating behavior. We should gear the opening phase of the psychotherapy process toward building a therapeutic alliance. Patients may experience early interpretations as though someone else was telling them what they feel and thereby minimizing and invalidating their own experiences. Therapists who empathize with patients' points of view and take an active interest in what their patients think and feel, however, convey to patients that their autonomy is respected. Above all, psychotherapists must be flexible, persistent, and durable in the face of patients' tendencies to defeat any efforts to help them.

Pharmacotherapy. Pharmacologic studies have not yet identified any medication that yields a definitive improvement of the core symptoms of anorexia nervosa. Some reports support the use of atypical antipsychotics, particularly olanzapine, for weight gain, although larger studies or meta-analyses have not supported this. When using atypical antipsychotics, the metabolic and cardiac risks associated with these medications, particularly in a population already at risk for cardiac complications, require close monitoring. Antidepressants, including selective serotonin reuptake inhibitors (SSRIs) and tricyclic antidepressants (TCAs), have been tried by patients with anorexia nervosa with variable results, though typically antidepressants are not helpful while patients are in an undernourished state. In patients with anorexia nervosa and coexisting depressive disorders, we should treat the depressive condition. Concern exists about the use of tricyclic drugs in low-weight, depressed patients with anorexia nervosa, who may be vulnerable to hypotension, cardiac arrhythmia, and dehydration. In some patients, the depression improves with weight gain and normalized nutritional status.

Treatment of Bulimia Nervosa

Most patients with uncomplicated bulimia nervosa do not require hospitalization. In general, patients with bulimia nervosa are not as secretive about their symptoms as patients with anorexia nervosa. Therefore, outpatient treatment is usually not difficult, but psychotherapy is frequently stormy and prolonged. In some cases—when eating binges are out of control, outpatient treatment does not work, or a patient exhibits such additional psychiatric symptoms as suicidality and substance abuse—hospitalization may become necessary. Also, electrolyte and metabolic disturbances resulting from severe purging may necessitate hospitalization.

Psychotherapy

COGNITIVE-BEHAVIORAL THERAPY. CBT should be considered the benchmark, first-line treatment for bulimia nervosa. The data supporting the efficacy of CBT are based on strict adherence to rigorously implemented, highly detailed, manual-guided treatments that include about 18 to 20 sessions over 5 to 6 months. CBT implements several cognitive and behavioral procedures to (1) interrupt the self-maintaining behavioral cycle of binging and dieting and (2) alter the individual's dysfunctional cognitions; beliefs about food, weight, body image; and overall self-concept.

OTHER MODALITIES. Given its effectiveness in anorexia nervosa, clinicians have also used FBT for bulimia nervosa. Additionally, controlled trials have shown that a variety of novel ways of administering and facilitating CBT are effective for bulimia nervosa. These include "stepped-care" programs and internet-based platforms, computer-facilitated programs, email-enhanced programs, and administration of CBT via telemedicine to remote areas. Finally, emerging evidence suggests that dialectical behavior therapy may be effective.

Pharmacotherapy. Antidepressant medications help treat bulimia nervosa, particularly the SSRI fluoxetine. Fluoxetine can reduce binge eating and purging, independent of the presence of a mood disorder. Dosages of fluoxetine that are effective in decreasing binge eating, however, may be higher (60 to 80 mg a day) than those used for depressive disorders. Other

antidepressants that may be helpful include other SSRIs (although concerns about prolonged QT intervals with higher doses limit the utility of citalopram in this population), TCAs (particularly amitriptyline and desipramine), trazodone, and monoamine oxidase inhibitors (MAOIs). Bupropion is contraindicated due to an increased risk of seizure in this population. In general, most of the antidepressants other than fluoxetine have been effective at dosages usually given in the treatment of depressive disorders. Medication is helpful in patients with comorbid depressive disorders and bulimia nervosa. Topiramate may have some efficacy in reducing binge episodes in bulimia nervosa, as may lisdexamfetamine. Evidence indicates that CBT and medications (particularly fluoxetine) are the most effective combination.

Treatment of Binge-Eating Disorder

Psychotherapy. CBT is the most effective psychological treatment for binge-eating disorder and should be considered a first-line treatment. CBT can lead to decreases in binge eating and associated problems (e.g., depression); however, studies have not shown marked weight loss as a result of CBT. CBT combined with psychopharmacological treatments such as SSRIs shows better results than CBT alone. Exercise has also shown a reduction in binge eating when combined with CBT. Interpersonal psychotherapy (IPT) is also effective in the treatment of binge-eating disorder; however, therapy focuses more on the interpersonal problems that contribute to the disorder rather than disturbances in eating behavior. There is also some evidence for the use of dialectical behavior therapy for binge-eating disorder.

Psychopharmacotherapy. Symptoms of binge eating may benefit from medication treatment, with strong evidence supporting the use of lisdexamfetamine for both weight loss and reduction of binge episodes. Antidepressant medications have demonstrated improvement in binge eating, but typically do not result in sustained weight loss; these include fluoxetine, fluvoxamine, citalopram, escitalopram, sertraline, duloxetine, and bupropion. The anticonvulsants topiramate and zonisamide may improve binge-eating disorder, particularly with moderate weight loss. Topiramate may also reduce binge episodes.

Most, but not all, studies show that medication added to CBT is more effective than medication alone. For example, studies indicate that CBT did better than fluvoxamine or desipramine as a monotherapy for binge-eating disorder; however, when CBT was combined with these agents, more improvement was seen in terms of weight loss compared with CBT alone.

Treating of Other Specified Feeding and Eating Disorder

Night-Eating Syndrome. Various studies have shown positive results in patients treated with SSRIs who showed improvement in nighttime awakenings, nocturnal eating, and post-evening caloric intake. Weight loss and a reduction in nocturnal eating are associated with an addition of topiramate to medication regimens.

In patients with comorbid major depression and night-eating syndrome, bright light therapy has shown to decrease depressed mood. CBT has also been helpful.

EPIDEMIOLOGY

Anorexia Nervosa

Although a substantial proportion of those diagnosed with subthreshold anorexia nervosa in DSM-IV now have a formal diagnosis in DSM-5, combined rates of subthreshold and threshold anorexia nervosa have remained relatively stable since the 1970s. Various studies have, however, documented a significant increase in incidence rates (the number of new cases in the population over a set time) in the high-risk group of 15- to 19-year-old females in recent years. It remains unclear if this increase signifies an earlier age of illness onset or more rapid recognition and intervention. Across all age groups and genders, a review of recent epidemiologic studies found that lifetime prevalence of DSM-5 anorexia nervosa is between 2.4 and 4.3 percent, approximately double the rate of cases diagnosed using DSM-IV criteria. Among girls and women, point prevalence estimates of DSM-5 anorexia nervosa is between 0.6 and 0.7 percent.

Although epidemiologic studies indicate that it may occur as many as ten times more frequently in females, anorexia nervosa does affect males. Recent

research suggests that the illness, which continues to be perceived by many as a female disorder, may be even more common in men and boys than previously believed. It may go unrecognized in men for a variety of reasons. In particular, men may be reluctant to seek treatment out of shame, and clinicians may be less likely to recognize the syndrome in male versus female patients. Historically, many consider anorexia nervosa to be a disease of white, wealthy women; however, it impacts individuals of all racial and socioeconomic backgrounds.

Bulimia Nervosa

As with anorexia nervosa, rates of bulimia nervosa have increased with changes to diagnostic criteria. However, before the recent modifications appearing in DSM-5, studies suggested that the incidence of the illness had decreased in recent years. Using DSM-5 criteria, the lifetime prevalence of bulimia nervosa in women is approximately 2 percent, and point prevalence is close to 0.6 percent. The average age of onset also seems to have decreased, although this finding may be an artifact of earlier detection. Like anorexia nervosa, the disorder is more common in women than in men.

Binge-Eating Disorder

Binge-eating disorder is the most common eating disorder and the least gender-divided of the three. In the United States, the lifetime prevalence of binge-eating disorder is about 3.6 percent for women and 2.1 percent for men. Rates of binge-eating disorder are particularly high in obese and overweight individuals.

Other Specified Feeding and Eating Disorder

Night-Eating Syndrome. Night-eating syndrome occurs in approximately 2 percent of the general population; however, it has a higher prevalence among patients with insomnia, obesity (10 to 15 percent), eating disorders, and other psychiatric disorders. The disorder usually begins in early adulthood.

ETIOLOGY

Biologic, social, and psychological factors are important to the cause of feeding and eating disorders. However, the precise mechanisms of causation remain elusive. Current theories posit that individuals with eating disorders, in particular, possess a set of predisposing traits (e.g., biologic, genetic, or personality vulnerability) which, when triggered by a precipitating event (e.g., the stress of puberty, the decision to go on a diet), result in illness. Once the illness sets in, several factors work to maintain it (e.g., the social rewards of weight loss, the effects of the starvation state in anorexia nervosa). A discussion of the current understanding of the etiology of feeding and eating disorders is detailed below.

Anorexia Nervosa

Genetic and Biologic Factors. Although we have not identified a specific gene in anorexia nervosa, several lines of evidence suggest that genetic vulnerability plays an important role in the development of the illness. Family studies, in particular, have provided useful information about genetic susceptibility, demonstrating that individuals with a family history of anorexia nervosa are much more likely than those with no family history to receive a diagnosis during their lifetime. The risk of developing the illness is up to 11 times greater in individuals with a first-degree relative who has experienced the illness. A relative with a history of a different eating disorder also increases this risk. Twin studies have demonstrated that concordance rates of anorexia nervosa are substantially higher in monozygotic twins as compared to dizygotic twins, suggesting that something more than the family environment is at play in increasing the odds of illness development. Studies of the serotonin transporter offer preliminary evidence that this gene may interact with environmental stressors to play a role in the development of anorexia, further emphasizing that a convergence of elements is necessary for illness development. Finally, once the illness sets in, the biologic and psychological changes to the body that occur in the starvation state, including depression and obsessionality, may help to maintain the illness.

Developmental Factors. Anorexia nervosa tends to develop during adolescence, suggesting that factors particular to this period may put individuals at risk for the syndrome. Adolescence represents a time of

increased biologic, psychological, and social change. The experience of going through puberty and experiencing changes to body shape or weight may serve as a major stressor for some, triggering or worsening body dissatisfaction and low self-esteem. Additionally, several major social and psychological transitions occur throughout adolescence, including identity and role formation, increasing independence from parents, and the initiation of romantic relationships. These stressors and others may work to catalyze the eating disorder.

Psychological Factors. Several psychological factors appear to confer added risk for developing anorexia nervosa. Certain personality traits, including high levels of perfectionism, self-discipline, harm avoidance, and self-criticism, are common in individuals with the illness. Individuals with the restricting subtype, in particular, exhibit low impulsivity and are much more likely to delay rewards than individuals without the illness. Cognitive inflexibility is usually prominent, as well. In a subset of individuals, mood and anxiety disorders or symptoms precede the development of the anorexia nervosa. OCD and obsessive-compulsive personality traits also appear to serve as vulnerability factors.

Environmental and Social Factors. Environmental and social factors, small and large, from experiences in the family or school setting to cultural ideals, may play a role in the development of anorexia nervosa. The influence of family functioning style as a potential predisposing factor remains controversial. No specific family functioning style appears to be either a necessary or sufficient requirement for developing an eating disorder. As in most psychiatric disorders, various family dysfunctional styles appear to act as nonspecific vulnerability factors and also hamper recovery.

Activities that emphasize weight may increase the probability of developing anorexia nervosa or another eating disorder. Ballet, gymnastics, modeling, and weight-restricted sports like wrestling or light-weight rowing may lead to preoccupation with body form and unhealthy attempts to control weight. As many of these activities likely select for individuals who are higher in perfectionism, another risk factor for anorexia nervosa, they may be even more likely to contribute to illness onset.

Although it is a common misperception that Western media causes eating

disorders, the cultural ideal of thinness, which is certainly perpetuated by the media, may fuel the overvaluation of shape and weight that marks both anorexia nervosa and bulimia nervosa. Indeed, studies in Fiji, where Western media was not available until the 1990s, showed a significant increase in cases of eating disorders following the introduction of Western television shows to the country. Nonetheless, classic anorexia nervosa remains rare, and research has firmly established that the media alone does not cause eating disorders.

Bulimia Nervosa

Genetic and Biologic Factors. As in anorexia nervosa, genetics likely play a role in the development of bulimia nervosa, as evidenced by twin and family studies. Individuals with a family history of bulimia nervosa, mood disorder, substance use disorder, or obesity are at higher risk for developing the syndrome.

Neurobiologic disturbances are also present in individuals with bulimia nervosa and may increase the probability of binge eating. In particular, individuals with the disorder tend to display delayed gastric emptying, increased stomach capacity, and reduced secretion of cholecystokinin (CCK), a peptide hormone released by the small intestine that helps to signal satiety during food consumption. Together, disruptions to these neurobiologic processes may put individuals at elevated risk for overeating.

Developmental Factors. The same psychological and social stressors of puberty and adolescence that put individuals at risk for anorexia nervosa also confer risk for bulimia nervosa.

Psychological Factors. Unlike individuals with anorexia nervosa, those with bulimia nervosa tend to exhibit high levels of novelty seeking and impulsivity. They also tend to display elevated levels of harm avoidance, negative emotionality, and stress reactivity. Afflicted individuals are more likely than others to experience a comorbid substance use disorder and engage in self-harm, leading to speculation that a subset of individuals with bulimia nervosa may have a propensity toward impulsivity across a range of problematic behaviors. Mood and anxiety disturbances appear to serve as risk

factors for bulimia nervosa, as well.

Just as the starvation state works to maintain anorexia nervosa, the cycle of binge eating and purging often becomes self-sustaining in bulimia nervosa. Individuals with bulimia nervosa tend to restrict their food intake outside of binge episodes, which puts them at increased risk for episodes of overeating. In turn, after experiencing a binge episode and the resulting compensatory behaviors, individuals often renew their commitment to restrictive eating in an attempt to avoid future overeating episodes. Thus, this cycle tends to become self-perpetuating and works to maintain the disorder.

Environmental and Social Factors. Individuals with bulimia nervosa are likely affected by similar environmental and social stressors as those with anorexia nervosa.

Binge-Eating Disorder

We know even less about the etiology of binge-eating disorder than of anorexia or bulimia nervosa. Research thus far has suggested that a history of childhood obesity, mood disorder, and negative family dynamics may put individuals at higher risk for developing the illness. In some individuals, dietary restriction appears to play a role in precipitating episodes of binge eating, as in bulimia nervosa. Many individuals with binge-eating disorder, however, seem to experience binge eating outside of the context of dietary restriction. For these individuals, intense emotions may provoke binge episodes.

Other Specified Feeding and Eating Disorder

Night-Eating Syndrome. We also know little about the cause of night-eating disorder. However, researchers have studied the hormones melatonin, leptin, ghrelin, and cortisol as they relate to this disorder. Night-eating syndrome also appears to run in families.

Elimination Disorders

The developmental milestones of mastering control over bowel and bladder function are complex processes that involve motor and sensory functions, coordinated through frontal lobe activities, and regulated by neurons in the pons and midbrain area. Mastery of bowel and bladder function occurs over several months for the typical toddler. Infants generally void small volumes of urine approximately every hour, commonly stimulated by feeding, and may have incomplete emptying of the bladder. As the infant matures to be a toddler, bladder capacity increases, and between 1 and 3 years of age, cortical inhibitory pathways develop that allow the child to have voluntary control over reflexes that control the bladder muscles. The ability to have muscular control over the bowel occurs even before bladder control for most toddlers, and the assessment of fecal soiling includes determining whether the clinical presentation occurs with or without chronic constipation and overflow soiling. The typical sequence of developing control over bowel and bladder functions is the development of nocturnal fecal continence, diurnal fecal continence, diurnal bladder control, and nocturnal bladder control. Bowel and bladder control develops gradually over time. Toilet training is affected by many factors, such as a child's intellectual capacity and social maturity, cultural determinants, and the psychological interactions between child and parents. The ability to control bowel and bladder functions depends on the maturation of neurobiologic systems, so that children with developmental delays may also display delayed continence of bowel and bladder. When children exhibit incontinence of urine or feces regularly, it is troubling to the children and families, and often misunderstood as voluntary misbehavior.

Encopresis (repeated passage of feces into inappropriate places) and enuresis (repeated urination into bed or clothes) are the two elimination

disorders described in DSM-5. ICD-10 contains the diagnoses of nonorganic encopresis and enuresis, which they list in the category of other behavioral and emotional disorders with onset usually occurring in childhood and adolescence. We should not make these diagnoses until after age 4 years, for encopresis, and after age 5 years for enuresis, the ages at which a typically developing child masters these skills. Healthy development encompasses a range of time in which a given child can devote the attention, motivation, and physiologic skills to exhibit competency in elimination processes.

We discuss each disorder separately in this chapter.

ENCOPRESIS

Clinical and Diagnostic Features

According to both DSM-5 and ICD-10, encopresis occurs when a child passes feces into inappropriate places regularly. Table 14-1 compares the diagnostic approaches for encopresis. Encopresis may be present in children who have bowel control and intentionally deposit feces in their clothes or other places for a variety of emotional reasons. Anecdotal reports have suggested that occasionally encopresis is attributable to an expression of anger or rage in a child whose parents have been punitive or of hostility at a parent. In a case such as this, once a child develops this inappropriate repetitive behavior eliciting negative attention, it is difficult to break the cycle of continuous negative attention. In other children, sporadic episodes of encopresis can occur during times of stress—for example, proximal to the birth of a new sibling—but in such cases, the behavior is usually transient and does not fulfill the diagnostic criteria for the disorder.

Encopresis can also be present on an involuntary basis in the absence of physiologic abnormalities. In these cases, a child may not exhibit adequate control over the sphincter muscles, either because the child is absorbed in another activity or because he or she is unaware of the process. The feces may be of normal, near-normal, or liquid consistency. Some involuntary soiling occurs from chronic retaining of stool, which may result in a liquid overflow. In rare cases, the involuntary overflow of stool results from psychological causes of diarrhea or anxiety disorder symptoms. DSM-5 includes specifiers to indicate whether or not the disorder includes

constipation and overflow incontinence.

   Studies have indicated that children with encopresis who do not have gastrointestinal illnesses have high rates of abnormal anal sphincter contractions. This finding is particularly prevalent among children with encopresis with constipation and overflow incontinence who have difficulty relaxing their anal sphincter muscles when trying to defecate. Children with constipation, who have difficulties with sphincter relaxation, are not likely to respond well to laxatives in the treatment of their encopresis. Children with encopresis without abnormal sphincter tone are likely to improve over a short period.

Jack was a 7-year-old boy with daily encopresis, enuresis, and history of hoarding behaviors, along with hiding the feces around the house. He lived with his adoptive parents, having been removed from his biologic parents at the age of 3 years because of neglect and physical abuse. He was reported to be cocaine-addicted at birth but was otherwise healthy. Jack's biologic mother was a known methamphetamine and alcohol user, and his father had spent time in jail for drug dealing. Jack had always been enuretic at night, and until this year, he had a history of daytime enuresis as well. Jack had a short attention span, was highly impulsive, and had great difficulty staying in his seat at school and remaining on task. He had reading difficulties and was in a contained special education classroom because of his disruptive behavior as well as his academic difficulties. Despite experiencing physical abuse, he has not experienced flashbacks or other symptoms that would indicate the presence of posttraumatic stress disorder. Jack was treated for attention-deficit/hyperactivity disorder (ADHD) with a good response to methylphenidate.

**Table 14-1
Encopresis**

	DSM-5	ICD-10
Name	**Encopresis**	**Nonorganic**

		Encopresis
Duration	≥1/mo for ≥3 mo	
Symptoms	Eliminating feces in clothes or floor Can be voluntary or unintentional	Eliminating feces in inappropriate places Can be voluntary or unintentional
Exclusion	Age <4 y Substance use Another medical condition (not including ones that are causing constipation)	Another medical condition
Severity specifiers	With constipation and overflow incontinence Without constipation and overflow incontinence	

Jack's adoptive family sought help at a university hospital's outpatient program that had expertise in the behavioral treatments of many psychiatric disorders, including encopresis. The treatment program combined the use of regular laxatives and a bowel training method with cognitive-behavioral therapy for Jack and his family. Jack was started on a regimen of daily polyethylene glycol (PEG) solution and was seen by a pediatrician who was able to perform a manual disimpaction under sedation. Following that, Jack was continued on daily PEG solution combined with therapy. He learned to empty his bowel while sitting on the toilet for 10 minutes after each meal, whether or not he felt like he had to go. He soon was eager to stay on this regular bathroom schedule and felt proud when he was able to have a bowel movement in the toilet. Over 3 months, Jack improved, and at 6 months, he was almost entirely better. (Courtesy of Edwin J. Mikkelsen, M.D. and Caroly Pataki, M.D.)

Pathology and Laboratory Examination

Although no specific test indicates a diagnosis of encopresis, clinicians must rule out medical illnesses, such as Hirschsprung disease, before making a diagnosis. The physician should perform an abdominal examination to help determine whether fecal retention is responsible for encopresis with constipation and overflow incontinence, and an abdominal x-ray can help determine the degree of constipation present. Tests to determine whether sphincter tone is abnormal are generally not conducted in uncomplicated cases of encopresis.

Differential Diagnosis

In encopresis with constipation and overflow incontinence, constipation can begin as early as the child's first year and can peak between the second and fourth years. Soiling usually begins by age 4. There are frequent liquid stools and hard fecal masses in the colon and the rectum on abdominal palpation and rectal examination. Complications include impaction, megacolon, and anal fissures.

The chief differential medical problem is aganglionic megacolon or Hirschsprung disease, in which a patient may have an empty rectum and no desire to defecate, but may still have an overflow of feces. The disorder occurs in 1 in 5,000 children; signs appear shortly after birth. Faulty nutrition is rarely the cause of encopresis with constipation and overflow incontinence. Other conditions are rare as well, including structural disease of the anus, rectum, and colon, adverse drug effects, or nongastrointestinal medical (endocrine or neurologic) disorders.

Course and Prognosis

The outcome of encopresis depends on the etiology, the chronicity of the symptoms, and coexisting behavioral problems. In some cases, encopresis is self-limiting, and it rarely continues beyond middle adolescence. Encopresis in children who have associated physiologic factors, such as poor gastric motility and an inability to relax the anal sphincter muscles, is more challenging to treat than that in those with constipation but normal sphincter tone.

Encopresis is a particularly objectionable disorder to family members, who

may assume that the behavior is due to "laziness," and family tensions are often high. Peers are intolerant of the developmentally inappropriate behavior and typically taunt and reject a child with encopresis. Many affected children have abysmally low self-esteem and feel constant social rejection. Psychologically, a child may appear blunted toward the symptoms or less frequently may be entrenched in a pattern of encopresis as a mode of expressing anger. The outcome of encopresis is influenced by a family's willingness and ability to participate in treatment without being overly punitive and by the child's ability and motivation to engage in treatment.

Treatment

A typical treatment plan for a child with encopresis includes daily oral administration of laxatives such as PEG at 1 g/kg per day, and often a surgical disimpaction under general anesthesia before administering maintenance laxatives. Also help is a cognitive-behavioral intervention to help the child begin regular attempts to have bowel movements in the toilet, and to diminish anxiety related to bowel movement. By the time a child presents for treatment, considerable family discord and distress are common. We must reduce family tensions about the symptom and establish a nonpunitive atmosphere. Similarly, we should help to reduce the child's embarrassment at school. A treatment plan may include arranging for many changes of underwear with a minimum of embarrassment. Education of the family and correction of misperceptions that a family may have about soiling must occur before treatment. Laxatives are not necessary for children who are not constipated and do have reasonable bowel control, but regular timed intervals on the toilet may be useful with these children as well.

A report confirms the success of an interactive parent–child family guidance intervention for young children with encopresis based on psychological and behavioral interventions for children younger than age 9 years.

Supportive psychotherapy and relaxation techniques may be useful in treating the anxieties and other sequelae of children with encopresis, such as low self-esteem and social isolation. Family interventions can be helpful for children who have bowel control but who continue to deposit their feces in inappropriate locations. An optimal outcome occurs when a child achieves a

feeling of control over his or her bowel function.

Epidemiology

Encopresis affects about 3 percent of 4-year-olds and 1.6 percent of 10-year-old children. Incidence rates for encopretic behavior decrease drastically with increasing age. Between the ages of 10 and 12 years, it affects about 0.75 percent of typically developing children. Globally, the community prevalence of encopresis ranges from 0.8 to 7.8 percent. In Western cultures, bowel control is established in more than 95 percent of children by their fourth birthday and 99 percent by the fifth birthday. Encopresis is virtually absent in youth with normal intellectual function by the age of 16 years. Males are from three to six times more likely to have encopresis than females. A significant relationship exists between encopresis and enuresis.

Etiology

Ninety percent of chronic childhood encopresis is likely functional. Children with this disorder typically withhold feces by contracting their gluteal muscles, holding their legs together, and tightening their external anal sphincter. In some cases, this is an entrenched behavioral response to previously painful bowel movements due to hard stool, which leads to fear of defecation and withholding behaviors. Encopresis involves an often-complicated interplay between physiologic and psychological factors leading to an avoidance of defecation. However, when children chronically hold in bowel movements, the result is often fecal impaction and eventual overflow soiling. This pattern occurs in more than 75 percent of children with encopretic behavior. This standard set of circumstances in most children with encopresis supports a behavioral intervention with a focus on ameliorating constipation while increasing appropriate toileting behavior. Inadequate training or the lack of appropriate toilet training may delay a child's attainment of continence.

Evidence indicates that some encopretic children have lifelong inefficient and ineffective sphincter control. Other children may soil involuntarily, either because of an inability to control the sphincter adequately or because of excessive fluid caused by a retentive overflow.

In about 5 to 10 percent of cases, medical conditions cause fecal

incontinence, including abnormal innervation of the anorectal region, ultrashort-segment Hirschsprung disease, neuronal intestinal dysplasia, or spinal cord damage.

One study found encopresis to occur with significantly higher frequency among children with known sexual abuse and other psychiatric disorders, compared to samples of healthy children. Encopresis, however, is not a specific indicator of sexual abuse.

It is evident that once a child has developed a pattern of withholding bowel movements and attempts to defecate have become painful, the child's fear and resistance to changing the pattern are high. Battles with parents who insist that their untreated child attempts to defecate may aggravate the condition and cause secondary behavioral difficulties. Untreated children with encopresis, however, frequently end up being socially ostracized and rejected. The social consequences of soiling can lead to the development of emotional problems. On the other hand, children with encopresis who clearly can control their bowel function adequately but chronically deposit feces of relatively normal consistency in abnormal places are likely to have pre-existing neurodevelopmental problems. Occasionally, a child has a specific fear of using the toilet, leading to a phobia.

Encopresis, in some cases, can be considered secondary, that is, emerging after a period of healthy bowel habits in conjunction with a disruptive life event, such as the birth of a sibling or a move to a new home. When encopresis manifests after a long period of fecal continence, it may reflect a regressive developmental behavior based on a severe stressor, such as parental separation, loss of a best friend, or unexpected academic failure.

Megacolon. Most children with encopresis retain feces and become constipated, either voluntarily or secondary to painful defecation. In some cases, a subclinical pre-existing anorectal dysfunction exists that contributes to constipation. In either case, the resulting chronic rectal distention from large, hard fecal masses can cause loss of tone in the rectal wall and desensitization to pressure. Thus, children in this situation become even less aware of the need to defecate, and overflow encopresis occurs, usually with relatively small amounts of liquid or soft stool leaking out.

ENURESIS

Clinical and Diagnostic Features

Enuresis is the repeated voiding of urine into a child's clothes or bed; the voiding may be involuntary or intentional. The child must exhibit a developmental or chronologic age of at least 5 years. Children with enuresis are at higher risk for ADHD compared with the general population. They are also more likely to have comorbid encopresis. DSM-5 and the ICD-10 break down the disorder into three types: nocturnal only, diurnal only, and nocturnal and diurnal (Table 14-2).

Pathology and Laboratory Examination

No single laboratory finding is pathognomonic of enuresis, but clinicians must rule out organic factors, such as the presence of urinary tract infections, which may predispose a child to enuresis. Structural obstructive abnormalities may be present in up to 3 percent of children with apparent enuresis. Usually, clinicians defer sophisticated radiographic studies in uncomplicated cases of enuresis with no signs of repeated infections or other medical problems.

Table 14-2
Enuresis

	DSM-5	ICD-10
Name	Enuresis	Nonorganic Enuresis
Duration	≥2/wk for ≥3 mo	
Symptoms	Urinating into bed or clothes Can be voluntary or unintentional	Involuntary voiding of urine Can be nighttime or daytime
Exclusions (not result of):	Age <5 y Substance use Another	Another medical condition (i.e., structural abnormality, epilepsy, neurologic disorder)

	medical condition
Symptom specifiers	Nocturnal only
	Diurnal only
	Nocturnal and Diurnal

Differential Diagnosis

Medical causes of bladder dysfunction must be investigated and ruled out. Urinary tract infections, obstructions, or anatomical conditions are found most often in children who experience both nocturnal and diurnal enuresis combined with urinary frequency and urgency. We should consider various causes of genitourinary pathology. Depending on the signs and symptoms, these can include obstructive uropathy, spina bifida occulta, and cystitis— there are many other causes of polyuria and enuresis, such as diabetes mellitus and diabetes insipidus. Also, we should consider disturbances of consciousness and sleep, such as seizures, intoxication, and sleepwalking disorder, during which a child urinates; and adverse effects from medications.

Course and Prognosis

Enuresis is often self-limited, and a child with enuresis may have a spontaneous remission. Most children who master the task of control over their bladder gain self-esteem and improved social confidence when they become continent. About 80 percent of affected children have never achieved a year-long period of dryness. Enuresis after at least 1 dry year usually begins between the ages of 5 and 8 years; if it occurs much later, especially during adulthood, we should investigate for other causes. Some evidence indicates that the late onset of enuresis in children is more frequently associated with a concomitant psychiatric difficulty than is enuresis without at least 1 dry year. Relapses occur in children with enuresis who are becoming dry spontaneously and in those in treatment. The significant emotional and social difficulties of these children usually include poor self-image, decreased self-esteem, social embarrassment and restriction, and intrafamilial conflict. The course of children with enuresis may be influenced by whether they receive

appropriate evaluation and treatment for common comorbid disorders such as ADHD.

Treatment

A relatively high rate of spontaneous remission of enuresis occurs over time in childhood; however, in many cases, interventions are necessary because enuresis is causing functional impairment. The first step in any treatment plan is to review appropriate toilet training. If the parents have not attempted toilet training with the child, we should guide the parents and the patient in this undertaking. It is helpful to keep records, to determine a baseline, and follow the child's progress; it may also be therapeutic in itself. A star chart may be particularly helpful. Other useful techniques include restricting fluids before bed and night lifting to toilet train the child. Intervention with alarm therapy, which is triggered by wet underwear, has been a mainstay of treatment for enuresis. Alarm therapy works by alerting a child to respond when voiding begins during sleep. The alarm is a battery-operated device that can be attached to a child's underwear or a mat. The alarm is triggered as soon as voiding begins by emitting a loud noise that awakens the child. The success of this method depends on the child's ability to awaken promptly and respond to the alarm by getting up and voiding in the toilet. A child who can respond optimally is at least 6 or 7 years old.

Another simple intervention for children with enuresis and bowel dysfunction is to assess whether chronic constipation is contributing to urinary dysfunction and to consider increasing dietary fiber to diminish constipation.

Behavioral Therapy. Classical conditioning with the bell (or buzzer) and pad (alarm) apparatus is generally the most effective treatment for enuresis, with dryness resulting in more than 50 percent of cases. Bladder training—encouragement or reward for delaying micturition for increasing times during waking hours—has also been used. Although sometimes useful, this method is decidedly inferior to the bell and pad.

Pharmacotherapy. We can consider medication when enuresis is causing social, family or functional impairment, and when dietary and behavioral interventions are not sufficient. When the problem interferes significantly

with a child's functioning, we can consider several medications, although the problem often recurs when we discontinue the medications.

Desmopressin, an antidiuretic compound that is available as an intranasal spray, has shown success in reducing enuresis. The reduction of enuresis has varied from 10 to 90 percent with the use of desmopressin. In most studies, enuresis recurred shortly after discontinuation of this medication. Adverse effects that can occur with desmopressin include headache, nasal congestion, epistaxis, and stomachache. The most severe adverse effect reported with the use of desmopressin to treat enuresis was a hyponatremic seizure experienced by a child.

Antidepressants, particularly imipramine, were the first medications used for enuresis, and are still used at times. In this case, we are taking advantage of the anticholinergic side effects of the medication. However, it does have a considerable side effect profile. Reboxetine (not available in the United States), a norepinephrine reuptake inhibitor that has a noncardiotoxic side effect profile, may be a safer alternative to the classically used imipramine in the treatment of childhood enuresis.

Psychotherapy. Psychotherapy may be useful in dealing with coexisting psychiatric problems and the emotional and family difficulties that arise secondary to chronic enuresis. However, the behavioral therapy approaches described above are the treatments of choice.

Epidemiology

The prevalence of enuresis ranges from 5 to 10 percent in 5-year-olds. It is about 1.5 to 5 percent in 9- to 10-year-olds, and about 1 percent in adolescents 15 years and older. The prevalence of enuresis decreases with increasing age. Enuretic behavior is considered developmentally appropriate among young toddlers, precluding diagnoses of enuresis; however, enuretic behavior occurs in 82 percent of 2-year-olds, 49 percent of 3-year-olds, and 26 percent of 4-year-olds regularly.

Although most children with enuresis do not have a comorbid psychiatric disorder, children with enuresis are at higher risk for the development of another psychiatric disorder.

Nocturnal enuresis is about 50 percent more common in boys and accounts

for about 80 percent of children with enuresis. Diurnal enuresis is also seen more often in boys who often delay voiding until it is too late. A spontaneous resolution of nocturnal enuresis is about 15 percent per year. Nocturnal enuresis consists of an average volume of voided urine, whereas when a child voids small volumes of urine at night, other medical causes may be present.

Etiology

Enuresis involves complex neurobiologic systems that include contributions from cerebral and spinal cord centers, motor and sensory functions, and autonomic and voluntary nervous systems. Neurons regulate urination in the pons and midbrain regions. Bladder detrusor muscle contraction occurs whenever bladder capacity is reached, which can lead to enuresis in a sleeping child. Therefore, excessive volumes of urine produced at night may lead to enuresis at night in children without any physiologic abnormalities. Nighttime enuresis often occurs in the absence of a specific neurogenic cause. Daytime enuresis may develop based on behavioral habits developed over time.

Daytime enuresis may occur in the absence of neurologic abnormalities resulting from habitual, voluntary tightening of the external sphincter during urges to urinate. The pattern may become set in a young child who may start with a normal or overactive detrusor muscle in the bladder, but with repeated attempts to prevent leaking or urination when there is an urge to void. Over time, the sensation of the urge to urinate diminishes, and the bladder does not empty regularly, leading to enuresis at night when the bladder is relaxed and can empty without resistance. This immature pattern of urinating can account for some cases of enuresis, especially when the pattern has been in place since early childhood. Most children are not enuretic by intention or even with awareness until after they are wet. Physiologic factors often play a role in the development of enuresis, and behavioral patterns are likely to maintain the maladaptive urination. Healthy bladder control, which is acquired gradually, is influenced by neuromuscular and cognitive development, socioemotional factors, toilet training, and genetic factors. Difficulties in one or more of these areas can delay urinary continence.

Genetic factors play a role in the expression of enuresis, given that the emergence of enuresis is significantly higher in first-degree relatives. A

longitudinal study of child development found that children with enuresis were about twice as likely to have concomitant developmental delays as those who did not have enuresis. About 75 percent of children with enuresis have a first-degree relative who has or has had enuresis. A child's risk for enuresis is more than seven times higher if the father was enuretic. The concordance rate is higher in monozygotic twins than in dizygotic twins. There is a strong genetic component, and much can be accounted for by tolerance for enuresis in some families and by other psychosocial factors.

Studies indicate that children with enuresis with a normal anatomical bladder capacity report urge to void with less urine in the bladder than children without enuresis. Other studies report that nocturnal enuresis occurs when the bladder is full because of lower than expected levels of nighttime antidiuretic hormone. This low level of the hormone could lead to higher-than-usual urine output. Enuresis does not appear to be related to a specific stage of sleep or time of night; instead, bedwetting appears randomly. In most cases, the quality of sleep is average. Little evidence indicates that children with enuresis sleep more soundly than other children.

Psychosocial stressors appear to precipitate enuresis in a subgroup of children with the disorder. In young children, the disorder may relate to the birth of a sibling, hospitalization, the start of school, separation of a family due to divorce, or a move to a new environment.

Sleep–Wake Disorders

To understand sleep and its disorders, it helps to begin with sleep's three essential characteristics: (1) Sleep is a process required for proper brain function. Failure to sleep impairs thought processes, mood regulation, and a host of normal physiologic functions. (2) Sleep is not a single process; there are several distinct types of sleep. These different types of sleep differ both qualitatively and quantitatively. Each type of sleep has unique characteristics, functional importance, and regulatory mechanisms. Selectively depriving one particular type of sleep produces compensatory rebound when an individual is allowed to sleep ad lib. (3) Sleep is not a passive process; during sleep, there is a high degree of brain activation and metabolism.

The science of sleep is a fascinating ever-growing topic, that is, perhaps unfortunately, beyond the repertoire of the average psychiatrist, and we refer the interested reader to the Comprehensive Textbook's discussion of the basic science of sleep, discussed about the neural sciences.

Several basic mechanisms regulate sleep, and when these systems go awry, sleep disorders occur. Sleep disorders are both dangerous and expensive. Hypersomnolence is a serious, potentially life-threatening condition affecting not only the sleepy individual but also their family, coworkers, and society in general. Sleep-related motor vehicle accidents represent a significant public safety concern, with some states enacting criminal statutes to deter sleepy driving. Investigations link many major industrial catastrophes to sleepiness. Research shows that sleep-disordered breathing contributes to hypertension, heart failure, and stroke. Sleep disorders' direct cost per annum in the United States is about $16 billion, with indirect costs ranging upward to more than $100 billion.

THE CLINICAL PRESENTATION

This chapter's disorders all describe disturbances in healthy sleep. Among them, however, there is considerable variation.

It is helpful to understand the stages of sleep and electrophysiologic criteria. Table 15-1 and Figure 15-1 illustrate some of the features of normal sleep.

Insomnia Disorder

Persons with insomnia primarily have difficulty falling asleep, difficulty staying asleep, or trouble waking early with an inability to fall back to sleep, sufficient to impair their functioning. In children, this may manifest as resistance to caregiver designation of bedtime or difficulty sleeping without some sort of intervention from the caregiver.

Hypersomnolence Disorder

Hypersomnolence broadly refers to excessive sleepiness and time sleeping. During the day, people are drowsy and have reduced attention. Excessive sleepiness can be a serious, debilitating, potentially life-threatening condition. It affects not only the patient but their family, colleagues, and the public. Not due to disrupted sleep or circadian problems, hypersomnolence disorder likely results from some fundamental neurologic sleep regulation dysfunction.

Narcolepsy

People with narcolepsy have an overwhelming desire to sleep and may suddenly fall asleep, even if it is not appropriate to do so. Also, they may experience cataplexy, or the sudden loss of muscle tone, usually with continuing full or partial consciousness. Laughter, or other strong emotions, commonly precipitate the cataplexy. Cataplexy can range from transient weakness in the knees to total paralysis while the patient is fully conscious. Episodes may last from several seconds to minutes. Usually, the patient is unable to speak and may fall to the floor. Sleep paralysis and hypnagogic (or hypnopompic) hallucinations may occur.

Sleep-Related Breathing Disorders

People who present with sleep-related breathing disorders experience an interruption of normal respiration that impacts their sleep, often resulting in CNS arousal and, consequently, daytime sleepiness. Sleep-related breathing disorders include conditions involving large airway obstruction during sleep, breathing cessation resulting from central respiratory mechanisms, and hypoventilation without breathing cessation. Those affected may experience sleep-related breathing cessation (sleep apnea), in which the patient stops breathing for 10 seconds or more during sleep. They may instead have reduced breathing or *hypopnea.* Airway obstruction is the usual case of these impairments, however central (brainstem) pathology can also be the cause. When asleep, breathing cessations or reductions typically provoke CNS arousal, significant oxyhemoglobin desaturation, or both. Sleep apnea can *obstructive, central,* or *mixed,* depending on the cause.

The clinical presentation of the sleep-related breathing disorders varies depending on the mechanism of the disorder. Table 15-2 lists some of these symptoms.

Circadian Rhythm Sleep–Wake Disorders

Circadian rhythm sleep disorders include a wide range of conditions involving a misalignment between desired and actual sleep periods. This collection of sleep disorders shares the same primary underlying etiology—a desynchrony between an individual's internal circadian biologic clock and the desired or conventional sleep–wake cycle. The circadian pacemaker is in the suprachiasmatic nucleus (SCN). SCN firing oscillates with an almost sinusoidal pattern, the period of which is 24 hours, and the output correlates with the daily fluctuations in core body temperature. Mismatched circadian clock and desired schedules can arise from improper phase relationships between the two, travel across time zones, or dysfunctions in the basic biologic rhythm. Under normal circumstances, the internal circadian pacemaker is reset each day by bright light, social cues, stimulants, and activity. In cases in which these factors fail to reentrain the circadian rhythm, the circadian sleep disorders occur.

Table 15-1

Stages of Sleep—Electrophysiologic Criteria

	Electroencephalogram	Electrooculogram	Electrom
Wakefulness	Low-voltage, mixed frequency activity; α (8–13 cps) activity with eyes closed	Eye movements and eye blinks	High toni and vc mover
Non–rapid eye movement sleep			
Stage 1	Low-voltage, mixed frequency activity; θ (3–7 cps) activity, vertex sharp waves	Slow eye movements	Tonic act slightl decrea from wakef
Stage 2	Low-voltage, mixed frequency background with sleep spindles (12–14 cps bursts) and K complexes (negative sharp wave followed by positive slow wave)	None	Low toni
Stage 3	High-amplitude (≥75 μV) slow waves (≤2 cps) occupying 20–50% of epoch	None	Low toni
Stage 4	High-amplitude slow waves occupy >50% of epoch	None	Low toni

REM sleep	Low-voltage, mixed frequency activity; saw-tooth waves, θ activity, and slow α activity	REMs	Tonic ato phasic twitch

cps, cycles per second; REM, rapid eye movement.

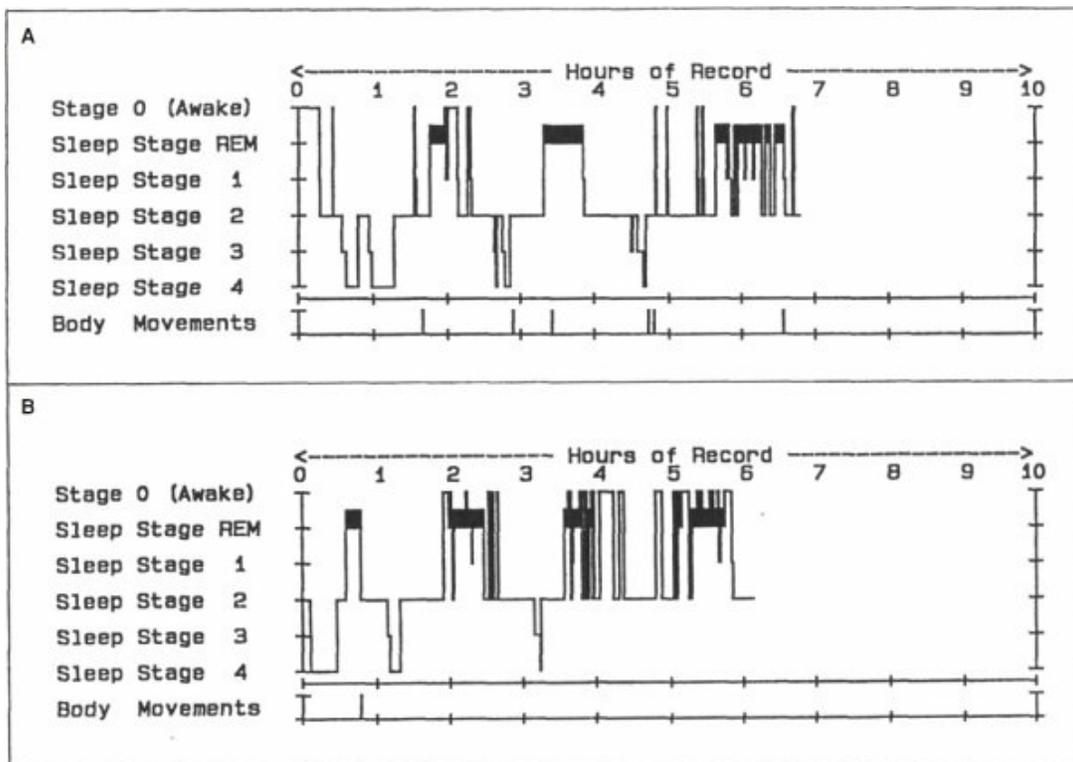
Criteria from Rechtschaffen A, Kales A. *A Manual of Standardized Terminology, Techniques, and Scoring System for Sleep Stages of Human Subjects*. Los Angeles, CA: Brain Information Service/UCLA Brain Research Institute; 1968, with permission.


FIGURE 15-1

Sleep histograms showing normal sleep and insomnia. Sleep stage histograms comparing normal sleep (**Panel A**) with that found in a patient with major depressive disorder (**Panel B**). Difficulty maintaining sleep and early morning awakenings are common complaints in patients with depression. **Panel B** illustrates the electrophysiologic correlates of these complaints beginning, in this case, after approximately 2 hours of sleep. Sleep continuity becomes disrupted as morning approaches. Also present is a markedly reduced latency to REM sleep. This sleep feature is characteristic of this patient population and is thought by some to reflect cholinergic–aminergic imbalance.

Table 15-2

Sleep Apnea Symptoms Based on Cause

Obstructive Sleep Apnea

Excessive sleepiness

Snoring

Obesity

Restless sleep

Nocturnal awakenings with choking or gasping for breath

Morning dry mouth

Morning headaches

Heavy nocturnal sweating

Central Sleep Apnea

Breathing cessations unrelated to airway flow limitations

Insomnia

Daytime sleepiness

Morning headaches

Parasomnias and Sleep-Related Movement Disorders

Parasomnias are disorders of partial arousal. In general, the parasomnias are a diverse collection of sleep disorders characterized by physiologic or behavioral phenomena that occur during or are potentiated by sleep. One conceptual framework views many parasomnias as overlaps or intrusions of one sleep–wake state into another. Usually, we divide sleep into three basic states: wakefulness, non–rapid eye movement (NREM) sleep, and REM. Each has a unique neurologic organization. During wakefulness, both the body and brain are active. In NREM sleep, both the body and brain are much less active. REM sleep, however, pairs an atonic body with an active brain (capable of creating elaborate dream fantasies). Regional cerebral blood flow, magnetic resonance imaging (MRI), and other imaging studies confirm increased brain activation during REM sleep. It certainly appears that in some parasomnias, there are state boundary violations. For example, arousal disorders (sleepwalking and sleep terrors) involve momentary or partial wakeful behaviors suddenly occurring in NREM sleep. Similarly, isolated sleep paralysis is the persistence of REM sleep atonia into the wakefulness

transition, whereas REM sleep behavior disorder (RBD) is the failure of the mechanism creating paralytic atonia such that individuals act out their dreams.

There are many sleep-related movement disorders. These disorders typically involve relatively simple bodily movements that impact sleep. Table 15-3 lists examples of these disorders.

DIAGNOSIS

Three different nosologies provide classification systems for sleep disorders: (1) the Diagnostic and Statistical Manual of Mental Disorders, fifth edition (DSM-5), (2) the International Classification of Sleep Disorders, third edition (ICSD-3), and (3) the International Classification of Diseases, 10th edition (ICD-10). Most general psychiatrists use the DSM-5 approach. However, Sleep Medicine specialists often prefer the ICSD-3. We have included a listing of ICSD sleep–wake disorders for reference (Table 15-4).

    Medications
    Substances

Insomnia Disorder

The primary diagnostic criteria descriptively relate to how insomnia affects sleep. To be diagnosed with insomnia, the person must have difficulty falling

asleep, staying asleep, or waking early with difficulty getting back to sleep. While there are no formal criteria for diagnostic subtypes of insomnia, the ICSD-3 does describe each subtype briefly. We describe the insomnia subtypes here to highlight possible insomnia nuances and complications. We present a comparison of the different approaches to diagnosing insomnia in Table 15-5.

Psychophysiologic Insomnia. Psychophysiologic insomnia (PPI) involves conditioned arousal with the thought of sleeping. Objects related to sleep (e.g., the bed, the bedroom) likewise have become conditioned stimuli that evoke insomnia. Daytime adaptation is usually good; however, there can be extreme tiredness, and the affected person can become desperate. PPI often occurs in combination with stress and anxiety disorders, delayed sleep phase syndrome, and hypnotic use and withdrawal. Table 15-6 lists some typical characteristics of PPI.

DESCRIPTION

Ms. W is a 41-year-old, divorced white female presenting with a two- and one-half year complaint of sleeplessness. She has some difficulty falling asleep (30- to 45-minute sleep-onset latency) and awakens every hour or two after sleep onset. These awakenings may last 15 minutes to several hours, and she estimates approximately 4.5 hours of sleep on an average night. She rarely takes daytime naps notwithstanding feeling tired and edgy. The patient describes her sleep problem with the following words, "It seems like I never get into a deep sleep. I have never been a heavy sleeper, but now the slightest noise wakes me up. Sometimes I have a hard time getting my mind to shut down." She views the bedroom as an unpleasant place of sleeplessness and states, "I tried staying at a friend's house where it is quiet, but then I couldn't sleep because of the silence."

At times, Ms. W is unsure whether she is asleep or awake. She has a history of clock watching (to time her wakefulness) but stopped doing this when she realized it was contributing to the problem. Reportedly the insomnia is unrelated to seasonal changes, menstrual cycle, or time-zone translocation. Her basic sleep hygiene is good. Appetite and libido are unchanged. She denies mood disturbance, except that she is quite

frustrated and concerned about sleeplessness and its effect on her work. Her work involves sitting at a microscope for 6 hours out of a 9-hour working day and meticulously documenting her findings. Her final output has not suffered, but she must now "double check" for accuracy.

She describes herself as a worrier and a Type-A personality. The patient does not know how to relax. For example, on vacation she continually worries about things that can go wrong. She will not even begin to unwind until she has arrived at the destination, checked in, and unpacked. Even then, she is unable to relax.

Medical history is unremarkable except for tonsillectomy (age 16 years), migraine headaches (current), and diet-controlled hypercholesterolemia. She takes naproxen as needed for headache. She does not currently drink caffeinated beverages, smoke tobacco, or drink alcoholic beverages. She does not use recreational drugs.

The problem with insomnia began after relocation to a new city and place of employment. She attributes her insomnia to the noisy neighborhood in which she now lives. She first sought treatment 18 months ago. Her family practice physician diagnosed depression, and she was started on fluoxetine that made her "climb the walls." Antihistamines were tried next with similar results. She was then switched to low-dose trazodone (for sleep) and developed nausea. After these medical interventions, she sought medical care elsewhere. Zolpidem 5 mg was prescribed, but it made her feel drugged and upon discontinuation she had withdrawal effects. Another family practice physician diagnosed "nonspecific anxiety disorder" and began buspirone; an experience she describes as "having an alien try to climb out of my skin." Buspirone was discontinued. Paroxetine was tried for 8 weeks with no effect. Finally, a psychiatrist was consulted, who diagnosed adult attention-deficit disorder (without hyperactivity) and suggested treatment with methylphenidate. At this point, the patient was convinced that a stimulant would not help her insomnia and demanded referral to a sleep disorders center.

DISCUSSION

Ms. W's symptoms fall into the broad category of an insomnia, and the symptoms began after having moved from one city to another. Environmental sleep disorder (noise) and adjustment sleep disorder (new

job, city, and apartment) are likely initial diagnoses. However, a more chronic, endogenous problem has become operative. What is it? Ms. W is a "worrier" and meticulous, but she doesn't reach diagnostic criteria for personality or anxiety disorders. Dyssomnia associated with mood disorder should be considered in any patient with sleep maintenance problems and early morning awakening insomnia. However, this patient does not have other significant signs of depression. Unfortunately, many patients are misdiagnosed with depression or "masked depression" on the sole basis of an insomnia complaint and unsuccessfully treated with antidepressant medication. Ms. W's job demands long hours with focused concentration. Her job performance has been superior for many years notwithstanding insomnia. Thus, a diagnosis of attention-deficit disorder is unlikely. Idiopathic insomnia implies a childhood complaint, which Ms. W denies.

The likely working diagnosis is PPI. There may be some sleep state misperception (sometimes unclear of whether she is awake or asleep), but this cannot adequately account for the constellation of symptoms. An initial treatment plan should include further documentation of the sleep pattern using a sleep log. Behavioral treatments will likely benefit this patient. Medications with sedative effects are sometimes useful during initial treatment of PPI. However, thus far in this patient they have done more harm than good. She is likely to be a challenging patient to treat.

Table 15-4
Outline of the International Classification of Sleep Disorders, Third Edition

I. Insomnia
    A. Chronic Insomnia Disorder
    B. Short-Term Insomnia Disorder
    C. Other Insomnia Disorder
    D. Isolated Symptoms and Normal Variants
        1. Excessive Time in Bed

    3. Sleep Starts (Hypnic Jerks)
VII. Other Sleep Disorders

Table 15-5
Insomnia Disorder

	DSM-5	ICSD-3	IC
Name	Insomnia disorder	Insomnia disorder	D
Duration	Symptoms occur at least 3 nights/wk, lasting at least 3 mo	Occurs at least 3×/wk	
Symptoms	Dissatisfaction with quality of sleep due to either: • Difficulty falling asleep • Difficulty	1. Problem with sleep initiation or maintenance 2. Symptoms occurring despite adequate opportunities for sleep 3. Symptoms resulting in daytime consequences due to poor sleep	D

	maintaining sleep • Early morning awakenings		
# Symptoms needed	Any of the above	All the above three symptoms	
Exclusion (not the result of):	Medical disorder A medication or substance Another sleep–wake disorder Insufficient opportunity for sleep		N N Sl Sl
Psychosocial impact	Causes significant distress and/or impairment in functioning	Required presence of significant daytime impairment/consequences due to impaired sleep	
Symptom specifiers	• **With non-sleep disorder mental comorbidity** (including substance use disorder) • **With other medical comorbidity** • **With other sleep disorder**		

Severity specifiers		
Course specifiers	**Episodic** (lasting 1–3 mo)	**Short-term insomnia disorder:** <3 mo
	Persistent (lasting ≥3 mo)	**Chronic insomnia disorder:** ≥3 mo
	Recurrent (two or more episodes occurring within 1 y)	
Comments		This is often occurring in the setting of an acute stressor

Idiopathic Insomnia. Idiopathic insomnia characterizes patients with a lifelong inability to obtain adequate sleep. The insomnia predates any psychiatric condition, and other etiologies must be ruled out or treated, including PPI, environmental sleep disturbances, and poor sleep hygiene.

Paradoxical Insomnia. Paradoxical insomnia, at its core, involves a dissociation between sleep and its usual attendant unconsciousness. In paradoxical insomnia, a person thinks he or she is awake and having insomnia even though the brain electrophysiologic activity pattern is consistent with the correlates of healthy sleep. We should consider this disorder when a patient complains of difficulty initiating or maintaining sleep without any objective evidence of sleep disruption. Paradoxical insomnia can occur in individuals who are free from psychopathology; however, it may represent a somatic delusion or hypochondriasis. Some patients with paradoxical insomnia have obsessional features regarding bodily functions.

Table 15-6
Some Characteristics of Psychophysiologic Insomnia

1. Excessive worry about not being able to sleep

2. Trying too hard to sleep
3. Rumination—inability to clear one's mind while trying to sleep
4. Increased muscle tension when getting into bed
5. Other somatic manifestations of anxiety
6. Ability to fall asleep when not trying (e.g., while watching television)
7. Sleeping better away from the person's own bedroom

Inadequate Sleep Hygiene. Inadequate sleep hygiene refers to insomnia produced by behaviors that are not conducive to good sleep. Many behaviors can interfere with sleep. Some of these behaviors increase arousal, for example, consuming caffeine or nicotine at night or engaging in excessive emotional or physical stimulation within a few hours of bedtime. Other behaviors interfere with sleep architecture, including daytime naps and a significant variation of the daily sleep–wake schedule.

Behavioral Insomnia of Childhood. Children with this subtype of insomnia depend on specific stimulation, objects, or setting for initiating or returning to sleep. Without the presence of, for example, a stuffed animal or a parent, the child has trouble falling asleep. Alternatively, without adequate limit-setting by the caregiver, bedtime stalling ("Dad, I'm thirsty—can I get some water?") or bedtime refusal ("I'm not tired! I don't want to go to sleep!") can ensue.

Insomnia Comorbid with Mental Disorder. This type of insomnia is the most common. Sleep disorder centers report that 35 percent of patients seen with insomnia have a mental disorder. Of these, major depressive disorder (MDD) is the most common disorder. Other common disorders include bipolar disorder, schizophrenia, and generalized anxiety disorder.

Insomnia Comorbid with Medical Condition. Insomnia accompanies many medical and neurologic conditions. Given pain's potential for disturbing sleep, all medical conditions producing pain can (and usually do) disturb sleep. Unfortunately, a synergy exists between pain and sleep, such that poor sleep lowers the pain threshold. This vicious cycle can present a difficult treatment challenge. However, reducing pain can also improve sleep,

and improving sleep can reduce pain. In other medical conditions, sleep disturbance appears to be secondary. For example, patients with sleep-related gastroesophageal reflux disease (GERD) often have insomnia. Treating the reflux results in sleep improvement but insomnia treatments seldom, if ever, relieve nocturnal GERD. Patients with chronic obstructive pulmonary disease (COPD) commonly suffer from both sleep-onset and sleep-maintenance insomnia. Neurodegenerative disorders are also frequently associated with sleep disorders.

Insomnia due to Drug or Substance. Many prescription drugs, even when taken properly, can disturb sleep. We list some common examples in Table 15-7.

Alcohol and hypnotic use initially promote sleep onset because of their sedating properties. A problem occurs when sleep quality is adversely affected, tolerance develops after chronic use, or withdrawal begins. Alcohol may relax a tense person and thereby decrease latency to sleep; however, sleep later in the night will usually be fragmented by arousals. As tolerance develops to the alcohol, higher amounts or more frequent dosing are needed to sustain the effects. Furthermore, during withdrawal or after tolerance develops, insomnia may rebound to a level more severe than the initial disturbance.

Table 15-7
Medications and Drugs Causing Insomnia

Antiparkinsonian drugs
Decongestants (e.g., pseudoephedrine)
Anorectics
Stimulants
Antiepileptic medications
SSRI antidepressants
Caffeine
Alcohol (rebound insomnia)
Sedatives (rebound insomnia)

Caffeine (the active ingredient in coffee) and theobromine (the active ingredient in chocolate) are methylxanthines and act as psychostimulants in the central nervous system (CNS). Psychostimulants increase sleep latency, reduce sleep efficiency, and decrease total sleep time. Caffeine's half-life is 3 to 7 hours and may interfere with sleep when consumed in large quantities throughout the day or even in smaller portions closer to bedtime. Some individuals are hypersensitive to methylxanthines, and any coffee or chocolate can trigger difficulty falling asleep or awakening after a couple of hours of sleep with difficulty getting back to sleep.

Finally, abuse of illicit substances, particularly stimulants (such as cocaine and amphetamines), interfere with sleep onset and sleep maintenance. Unlike with alcohol, discontinuation of these substances will cause hypersomnolence.

Hypersomnolence Disorder

DSM-5 includes hypersomnolence disorder as a discreet diagnosis, whereas ICSD and ICD consider it more broadly. ICSD refers to it as "idiopathic hypersomnia" and questions whether it is a single disorder or rather a group of disorders with different underlying causes. Table 15-8 compares the different approaches to diagnosing hypersomnolence.

In general, we should consider this disorder when a patient complains of frequently feeling sleepy despite getting adequate sleep. They may nap during the day. Despite getting adequate sleep, they do not feel refreshed when waking.

Kleine–Levin Syndrome. Kleine–Levin syndrome is a relatively rare condition consisting of recurrent periods of prolonged sleep (from which they are arousable) with intervening periods of healthy sleep and alert waking. During the episodes of hypersomnia, wakeful periods are usually marked by withdrawal from social contacts and return to bed at the first opportunity. Kleine–Levin syndrome is the best-recognized recurrent hypersomnia though it is uncommon. It predominantly afflicts males in early adolescence; however, it can also affect females and older people. With few exceptions, the first attack occurs between the ages of 10 and 21 years. However, there are some reports of onset in the fourth and fifth decades of life. In its classic

form, the recurrent episodes include extreme sleepiness (18- to 20-hour sleep periods), voracious eating, hypersexuality, and disinhibition (e.g., aggression). Episodes typically last for a few days up to several weeks and appear once to 10 times per year. A monosymptomatic hypersomnolent form can occur. The disorder is usually sporadic but familial cases are reported.

Narcolepsy

Table 15-9 lists the criteria for narcolepsy. People with narcolepsy have irresistible sleep episodes, lapses into sleep, or nap frequently.

The discovery that narcolepsy is strongly associated with a hypocretin (orexin) deficit radically changed diagnostic practice. Cataplexy had been considered a core feature of the disorder, but we now know that there are variants that occur without cataplexy.

Sleep-Related Breathing Disorders

DSM-5 includes three disorders under the category of sleep-related breathing disorders: obstructive sleep apnea-hypopnea, central sleep apnea, and sleep-related hypoventilation. Table 15-10 compares the diagnostic approaches to sleep-related breathing disorders.

Table 15-8
Hypersomnolence Disorder

	DSM-5	ICS-3	ICD-10
Name	Hypersomnolence disorder	Idiopathic hypersomnia	Nonorga hype
Duration	≥3×/wk for at least 3 mo

Comments	It is unclear whether this is a single disorder or multiple with different underlying mechanisms	This is u asso with othe disor

Obstructive Sleep Apnea-Hypopnea. Obstructive sleep apnea/hypopnea, often called obstructive sleep apnea (OSA), occurs when the airway partially or fully collapses during sleep. Decreased oxygen saturation and increased respiratory effort leads to arousals and sleep fragmentation. Predisposing factors for OSA include being male, reaching middle age, being obese, and having micrognathia (undersized lower jaw), retrognathia (posteriorly positioned lower jaw), nasopharyngeal abnormalities, hypothyroidism, and acromegaly. Patients with OSA may also have hypertension, erectile failure in men, depression, heart failure, nocturia, polycythemia, and memory impairment as a result of obstructive sleep apnea-hypopnea. Obstructive apnea and hypopnea episodes can occur in any stage of sleep but are more typical during REM sleep, NREM stage 1, and NREM stage 2 sleep.

Mr. J is a 28-year-old single African American male with an approximately 10-year history of fatigue and sleepiness in the daytime. He began to recognize the daytime sleepiness as a problem in his freshman year of college when he would fall asleep in class or in the dormitory. He admits that his sleep–wake schedule was disrupted during college due to taking long naps and then having to stay up until 1:00 or 2:00 am to complete his studies. His grades and social life suffered, and he describes himself as depressed, isolated, and hopeless about his planned future as a certified public accountant.

As a child, Mr. J says he slept "normally." In high school he felt best with 10 hours of sleep per night and was able to function well in the daytime. Mr. J denies abuse of alcohol or drugs. He does not use tobacco and drinks about 8 to 10 cups of coffee per day. Family history is

negative for known sleep or psychiatric disorders. Physical examination findings are noncontributory except for body mass index of 29. Routine labs were normal, including TSH.

Mr. J's excessive sleepiness has continued to the present day, notwithstanding some improved sleep hygiene. Improvements include more consistency in bedtime, trying not to nap, and a torturous month-long trial without caffeine. He remains dysphoric and discouraged about his future, blaming his chronic sleepiness as the continuing impediment to his life plans. "I'm just tired of being tired," he says.

Currently, his bedtime is between 10:00 and 10:30 pm; his wake-up alarm is set for 6:30 am. He oversleeps at least once a week on workdays and sleeps from 10:30 pm until 10:00 am on weekends to "catch up." He has difficulty awakening and feels unrefreshed or mildly refreshed. By drinking six to eight cups of coffee in the morning, he is usually able to avoid dozing during the morning. Luckily, he works independently and can schedule client appointments during this relatively alert time. After lunch he routinely falls asleep at the computer while working. He sleeps for 20 to 60 minutes and is usually awakened by his secretary. He then drinks another two cups of coffee and continues with his work. Unexpected napping can also occur later in the afternoon or evening, and he has "nodded off" while driving. He sleeps alone; however, he has been told that he snores loudly. He does not awaken gasping or choking. He denies hypnagogic hallucinations and sleep paralysis but thinks he may feel weak after the rare occasions when he participates in a heated argument.

DISCUSSION

Mr. J has one of the hypersomnias. Most consistent with his history are obstructive sleep apnea syndrome, idiopathic hypersomnia, sleep deprivation in a long sleeper, dyssomnia associated with mood disorder, and narcolepsy. The ancillary symptoms of narcolepsy are absent, with the possible exception of cataplexy. When cataplexy occurs clearly, the diagnosis of narcolepsy is strongly indicated. However, Mr. J's possible infrequent weakness during heated arguments is equivocal for cataplexy. His persistent desire for a 10-hour sleep period would be unusual for a patient with narcolepsy.

A long sleeper or an individual with idiopathic hypersomnia requires prolonged sleep periods and may awaken groggy as does Mr. J. The main differentiating feature is that whenever consistently given a chance to have a full nightly sleep period (usually 10 to 12 hours), the long sleeper does not experience excessive daytime sleepiness. Furthermore, there may be associated autonomic nervous system dysfunction or polysomnographic evidence of elevated slow-wave sleep percentage in patients with idiopathic hypersomnia.

Sleepiness associated with a low-grade chronic depression may be difficult to differentiate from other causes of hypersomnolence. Polysomnography, psychiatric interview, and psychometric testing can be helpful. Mr. J relates his dysphoria to sleepiness and not vice versa; nonetheless, a dyssomnia associated with mood disorder should be considered.

Obstructive sleep apnea syndrome is a strong possibly. Mr. J is overweight (BMI = 29) and snores loudly. Many patients are unaware of gasping or choking for breath. Often, family members witness cessation of breathing during sleep and urge patients to seek treatment. However, Mr. J lives and sleeps alone.

Polysomnography is recommended in patients suspected of obstructive sleep apnea syndrome, narcolepsy, or idiopathic hypersomnia. These disorders usually require lifelong treatment and have significant morbidity and mortality if untreated.

Symptom specifiers	**Narcolepsy without cataplexy but with**	**Types 1 and 2** (see	

	hypocretin deficiency	above)
	Narcolepsy with cataplexy but without hypocretin deficiency	
	Autosomal dominant cerebellar ataxia, deafness, and narcolepsy (due to genetic mutation and characterized by late onset in 30s and 40s)	
	Autosomal dominant narcolepsy, obesity, and type 2 diabetes (associated with mutation in myelin oligodendrocyte glycoprotein gene)	
	Narcolepsy secondary to another medical condition	
Severity specifiers	**Mild:** <1/wk, 1–2 naps daily mildly, or intermittently disturbed sleep. **Moderate:** cataplexy 1/day or close to that. Disturbed sleep, need for multiple naps. **Severe:** near constant.	

Multiple attacks/day.
Disturbed sleep.
Resistant to
medications.

Central Sleep Apnea. Central sleep apnea is a diminished effort to breathe. There are many possible causes, DSM defines three of them: idiopathic CSA, Cheyne–Stokes breathing, and CSA comorbid with opioid use. Other causes include heart failure, high altitude, brainstem lesions, metabolic conditions, specific drugs or substances (CNS depressants), congenital abnormalities, and positive airway pressure (PAP) treatment. The critical characteristic linking the various CSA syndromes is the diminished breathing is not caused by airway obstruction. ICSD-3 includes several subtypes of CSA in addition to those included in DSM-5, which we discuss below, along with the DSM-5 subtypes.

Table 15-10
Sleep-Related Breathing Disorders

Severe: apnea hypopnea index >30
Central Sleep Apnea:
Severity based on frequency of breathing disturbance as well as severity of oxygen desaturation/sleep fragmentation
Sleep-Related Hypoventilation:
Severity based on degree |

of hypoxemia/hypercarbia, in addition to presence of end-organ impairment. Blood gas abnormality during wakefulness is an indicator of more severe illness.

IDIOPATHIC CSA. Patients with idiopathic CSA typically have low normal arterial carbon dioxide tension ($PaCO_2$) while awake and have a high ventilatory response to CO_2. They present with daytime sleepiness, insomnia, or awakening with shortness of breath. Respiratory cessations during sleep are independent of ventilatory effort. Polysomnography reveals five or more central apneas per hour of sleep.

CHEYNE–STOKES BREATHING. Cheyne–Stokes breathing is a unique breathing pattern consisting of prolonged hyperpnea during which tidal volume gradually waxes and wanes in a crescendo–decrescendo fashion. The hyperpnea alternates with apnea and hypopnea episodes that are associated with reduced ventilatory effort. This pattern is most common in older men with congestive heart failure or stroke. As with idiopathic CSA, the patient presents with daytime sleepiness, insomnia, and awakening short of breath.

CSA COMORBID WITH OPIOID USE. This syndrome is the third subtype of CSA in DSM-5, specified if opioid use disorder is present. There is an association with chronic use of long-acting opioid medications and impairment of neuromuscular respiratory control leading to CSA.

CSA DUE TO HIGH-ALTITUDE PERIODIC BREATHING. Central apnea at sleep onset is universal at elevations above 7,600 m but can occur at 1,500 m in some individuals (especially with a rapid ascent). This subtype is no longer included in DSM-5 but may still have clinical significance. Periods of central apnea alternate with periods of hyperpnea in a 12- to 34-second cycle. This

response is an extension of normal respiratory control at sleep onset where medullary pH receptors raise their set-point and require lower pH to respond. At high altitudes, hyperventilation causes a hypocapnic alkalosis that reduces ventilation during sleep. Sleep architecture may suffer, with increased duration in stages 1 and 2 and less slow-wave sleep. REM sleep may not be affected.

CSA DUE TO MEDICAL DISORDER WITHOUT CHEYNE–STOKES BREATHING. This form of CSA is usually caused by a brainstem lesion associated with a wide range of variable etiologies. Cardiac and renal disorders can also cause central apnea. Diagnostic criteria require a polysomnographically verified rate of 5 or more central apneas and hypopneas per hour of sleep.

CSA DUE TO DRUG OR SUBSTANCE USE. A variety of drugs or drug combinations can provoke central apnea episodes, most notably long-acting opiates. However, other substances or medications can also alter neuromuscular control leading to CSA. Diagnostic criteria are a central apnea index (number of episodes per hour) of 5 or more per hour.

PRIMARY SLEEP APNEA OF INFANCY. This form of CSA involves prolonged apneas or hypopneas with concomitant hypoxemia, bradycardia, or both. This condition afflicts preterm neonates, presumably because their brainstems are not fully developed. The condition may be exacerbated by other medical problems that further compromise the infant's physiologic and developmental status.

Sleep-Related Hypoventilation. DSM-5 includes three types of sleep-related hypoventilation disorders: (1) idiopathic hypoventilation, (2) congenital central alveolar hypoventilation, and (3) comorbid sleep-related hypoventilation (which results from a medical disorder, such as a cervical spinal cord injury, COPD, or a neuromuscular disorder, for example). Polysomnography must demonstrate either episodes with elevated CO_2 levels and decreased respirations or, if not monitoring the CO_2, episodes of persistently low oxyhemoglobin levels that are not provoked by apnea or hypopnea.

Circadian Rhythm Sleep–Wake Disorders

DSM-5 lists six types of circadian rhythm sleep–wake disorders: delayed sleep phase type, advanced sleep phase type, irregular sleep–wake type, non–24-hour sleep–wake type, shift work type, and unspecified type. DSM-5 does not include jet lag type, but ICSD does. Table 15-11 compares the diagnostic approaches to the circadian rhythm sleep–wake disorders.

Table 15-11
Circadian Rhythm Sleep Disorders

	DSM-5	ICSD-3	ICD-10
Name	Circadian rhythm sleep-wake disorders	Circadian rhythm sleep–wake disorders: • **Shift work disorder** • **Jet lag disorder** • **Delayed sleep–wake phase disorder** • **Advanced sleep–wake phase disorder** • **Irregular sleep–wake rhythm disorder** • **Non–24-h sleep–wake rhythm disorder**	Disorders of sleep–wak schedule **Delayed slee phase syndrome** **Irregular slee wake patt**

Duration	**Episodic** (lasting 1–3 mo) **Persistent** (lasting ≥3 mo) **Recurrent** (two or more episodes occurring within 1 y)	Symptoms ≥3 mo (exception of jet lag disorder)	
Symptoms	• Disturbed sleep due to altered circadian rhythm • Excessive daytime sleepiness and/or insomnia	Chronic pattern of sleep–wake rhythm disruption due to abnormality in circadian timing/schedule Presence of insomnia and/or excessive sleepiness	Persistent slee disturbanc (i.e., insom or excessiv daytime sleepiness due to alter circadian rhythm and environme demands Disruption of normal 24- circadian cycle

	pattern, with daily drift of progressively later sleep onset/wake time) **Shift work type** **Unspecified type**	
Course specifiers	**Episodic** (lasting 1–3 mo) **Persistent** (lasting ≥3 mo) **Recurrent** (two or more episodes occurring within 1 y)	
Comments		Circadian rhythm disorders can be the result of underlying medical, psychiatric, or neurologic disorders

Delayed Sleep Phase Type. The delayed sleep phase circadian disorder occurs when the biologic clock runs slower than 24 hours or is shifted later than the desired schedule. This produces a phase delay in the sleepiness–alertness cycle. Individuals with delayed sleep phase are more alert in the evening and early nighttime, stay up later and are more tired in the morning. These individuals are sometimes called *night owls.*

Advanced Sleep Phase Type. Advanced sleep phase occurs when the circadian rhythm cycle shifts forward. Therefore, the sleepiness cycle moves earlier. Individuals with advanced sleep phase are drowsy in the evening, want to retire to bed earlier, awaken earlier, and are more alert in the early morning. Individuals with this pattern of advanced sleep phase are sometimes called *early birds* or *larks.*

Irregular Sleep–Wake Type. The irregular sleep–wake pattern occurs when the circadian sleep–wake rhythm is absent or pathologically diminished. The sleep–wake pattern is temporally disorganized, and the timing of sleep and wakefulness is unpredictable. Individuals with this condition have a healthy amount of sleep during 24 hours; however, it is fragmented into three or more episodes that occur irregularly. There are symptoms of insomnia at night and excessive sleepiness during the day. Long daytime naps and inappropriate nocturnal wakefulness occur. This usually impairs activities of daily life.

Non–24-Hour Sleep–Wake Type. When the circadian sleep–wake pacemaker has a cycle length greater or less than 24 hours and is not reset each morning, a person may develop this type of circadian rhythm disorder. Under normal circumstances, resynchronization of the circadian rhythm occurs daily in response to the light–dark cycle. Problems occur incrementally when internal and environmental clocks become more and more out of phase. If the circadian clock's period is longer than 24 hours and does not reset each day, the patient experiences progressively worsening sleep-onset insomnia and daytime sleepiness. Sleep problems peak when circadian and environmental clocks are 12 hours out of phase and then begin to lessen, as the sleep phase continues to advance. Eventually, the clocks align, and the sleep–wake cycle is normal for a few days. Then, unfortunately, the problem begins again.

For this reason, non–24-hour sleep–wake disorder has been called *periodic insomnia* and *periodic excessive sleepiness.* Traumatic brain injury (TBI) can cause this, as can blindness.

Shift Work Type. Many service industries require 24-hour operation (e.g., transportation, health care). Similarly, as cultures became more capital

intensive, mining and manufacturing became around-the-clock enterprises. The number of individuals doing shift work has been increasing steadily for decades. Shift workers commonly have insomnia, excessive sleepiness, or both. Some individuals require only a short time to adjust to a shift change, whereas others have great difficulty. Frequent shift rotation adds to the problem.

Furthermore, to meet social demands, shift workers often adopt an unshifted sleep–wake schedule on weekends and holidays. Even those individuals who try to stay shifted usually retain an unshifted circadian rhythm. The result can be severe insomnia when attempting to sleep and excessive sleepiness when attempting to remain awake. The result is profound sleep deprivation as circadian rhythm continues to conflict with the sleep–wake schedule. The natural low point in the normal sleep–wake rhythm occurs at approximately 3:00 to 5:00 AM—the time frame during which transportation and industrial accidents commonly occur as a direct consequence of sleepiness.

Jet Lag Type. Removed from DSM-5, the other classifications still recognize jet lag. With the advent of high-speed air travel, induced desynchrony between circadian and environmental clocks became possible. Thus, the term *jet lag* came into use. When an individual rapidly travels across many time zones, they either induce a circadian phase advance or a phase delay, depending on the direction of travel. Typically, traveling across one or two time zones will not cause a significant problem. However, it can be challenging to adjust to overseas travel. Individuals who frequently travel for business can find themselves quite impaired at the time they need to make crucial decisions.

Furthermore, "night owls" will experience greater difficulty adjusting to eastward travel because resynchronization requires phase advance. Similarly, "larks" theoretically will have more difficulty with westward travel. The number of time zones crossed is a critical factor. Usually, healthy individuals can quickly adapt to one or two time zone changes per day; therefore, natural adjustment to an 8-hour translocation may take 4 or more days.

Unspecified Type. During illnesses that keep patients bedridden during hospitalizations, and in some forms of dementia, individuals often sleep

erratically. The resulting chaotic sleep–wake pattern adversely affects the circadian rhythm. Medications can also exacerbate the sleep–wake cycle breakdown. Sleep in patients in the intensive care unit is disturbed by noise, light, and therapeutic and monitoring procedures. The resulting disorganized sleep–wake pattern can produce a significant sleep disorder. Also, abuse of recreational street drugs (e.g., methamphetamine, ecstasy) is associated with individuals remaining awake overnight or continuously for several days at a time. These episodes of prolonged wakefulness ultimately produce periods of profound hypersomnia.

Parasomnias and Sleep-Related Movement Disorders

DSM 5 includes only three of the 10 specific parasomnias referenced in the ICSD-3. Also, DSM-5 includes restless legs syndrome (RLS), which ICSD-3 classifies as one of the seven specific sleep-related movement disorders. We will discuss all of these disorders together.

NREM-Related Parasomnias. Table 15-12 compares the diagnostic approaches to the NREM-related parasomnias.

SLEEPWALKING. Sleepwalking, in its classic form, as the name implies, is a condition in which an individual arises from bed and ambulates without fully awakening. It is sometimes called somnambulism, and individuals can engage in a variety of complex behaviors while unconscious. Usually, sleepwalking occurs during slow-wave sleep, and characteristically begins toward the end of the first or second slow-wave sleep episodes. Sleep deprivation and interruption of slow-wave sleep appear to exacerbate, or even provoke, sleepwalking in susceptible individuals. Sleepwalking episodes may range from sitting up and attempting to walk to conducting an involved sequence of semipurposeful actions. The sleepwalker can often successfully interact with the environment (e.g., avoiding tripping over objects). However, the sleepwalker may interact with the environment inappropriately, which sometimes results in injury (e.g., stepping out of an upstairs window or walking into the roadway). There are cases in which sleepwalkers have committed acts of violence. An individual who is sleepwalking is difficult to awaken. Once awake, the sleepwalker will usually appear confused. It is best to gently attempt to lead sleepwalkers back to bed rather than to attempt to

awaken them by grabbing, shaking, or shouting. In their confused state, sleepwalkers may think they are being attacked and may react violently to defend themselves. Sleepwalking in adults is rare, has a familial pattern, and may occur as a primary parasomnia or secondary to another sleep disorder (e.g., sleep apnea). By contrast, sleepwalking is very common in children and has a peak prevalence between the ages of 4 and 8 years. After adolescence, it usually disappears spontaneously. Nightly to weekly sleepwalking episodes associated with physical injury to the patient and others are considered severe. There are "specialized" forms of sleepwalking, most notably sleep-related eating behavior.

DESCRIPTION

Ms. R is a 20-year-old white woman who was referred with symptoms of talking, mumbling, and crying out during sleep. At least twice per week she screams in her sleep. She is bothered with excessive sleepiness and falling asleep inappropriately, such as during a conversation. When inactive, she is tired and sleepy, even after a full 8-hour night of sleep. However, she has energy when motivated and leads a vigorous life. Once, she awakened outside of her apartment and her roommate had to let her back in because she had locked herself out. She does not recall the sleepwalking episode or other nocturnal wanderings but sometimes remembers yelling. From the history, crying seems to occur in light sleep but she rarely recalls any sleep-related thoughts or dreams. However, there is a history of occasional nightmares and bruxism. The patient uses an oral appliance to protect her teeth. Leg-kicking and mild snoring without gasping or choking are noted. The patient also complains of leg-kicking during sleep. Her sleep–wake schedule is irregular, and she averages between 5 and 7 hours of sleep per night. She occasionally awakens with a headache in the morning.

Previous health history includes a hospitalization for febrile convulsions during infancy, ophthalmologic surgery for strabismus during childhood, and tonsillectomy as a teenager. Health is otherwise excellent. The patient does not smoke tobacco or drink alcohol.

DISCUSSION

By history Ms. R has one or more of the parasomnias. Sleep talking alone does not require a sleep study, but this patient has nocturnal wanderings. Polysomnography with clinical EEG is indicated to rule out unrecognized nocturnal seizure disorder or other organic factors inducing sleepwalking. Sleepwalking is common and not necessarily considered abnormal in young children; however, in the adult it is rare and merits careful evaluation. Ms. R's excessive daytime sleepiness is likely due to insufficient sleep (5 to 7 hours per night) and possibly parasomnia-related disruption. Interestingly, many parasomnias are exacerbated by sleep deprivation, as is nocturnal seizure disorder.

Sleep studies were performed using comprehensive, attended, laboratory polysomnography. Prior to the overnight study, a clinical EEG was performed. The clinical EEG study did not reveal any significant abnormal EEG activity during baseline, photic stimulation, or hyperventilation. An extended EEG montage was used during the sleep study. Overall sleep quality was within the normal range. Sleep efficiency was 96 percent and latency to sleep was 1 minute. REM sleep percentage was elevated (31 percent) and latency to REM sleep was less than normal (57 minutes). Slow-wave sleep was normal in percentage, but EEG delta activity was very high amplitude. The overall macroarchitectural sleep pattern suggested rebound from sleep deprivation.

By contrast, sleep microarchitecture contained many abnormal features. The clinicians observed high amplitude paroxysmal EEG bursts. Excessively prolonged sleep spindles were noted, and rhythmic K complexes were observed. There was one arousal out of slow-wave sleep with rhythmic EEG discharges alternating with sharp waves. Sharps and spikes occurred several times; however, the focus was difficult to localize (possibly right temporal lobe). There were frequent body movements and full body jerks, most of which occurred during NREM sleep. There were episodes of moaning during slow-wave sleep and laughing during stage 2 sleep that was followed by high amplitude theta bursts and REM sleep. The clinicians observed frequent movements and arousals from REM sleep, but no REM-related spikes or sharp waves. Seizure-like EEG activity was noted during the night and occurred predominantly during slow-wave sleep. However, the patient did not attempt to sleepwalk.

Sharp wave and spike activity increased during the final 45 minutes of the sleep study.

The patient did not have any sleep-related breathing impairment and SaO_2 nadir was 90 percent. She had no periodic limb movements during sleep, and polygraphic features associated with RLS were absent.

SLEEP TERRORS. Sleep terrors involve sudden arousal with intense fearfulness. They usually begin with a piercing scream or cry and are accompanied by behavioral manifestations of intense anxiety bordering on panic. Autonomic and behavioral correlates of fear are typically present. Typically, an individual experiencing a sleep terror sits up in bed, is unresponsive to stimuli, and, if awakened, is confused or disoriented. Vocalizations may occur, but they usually are incoherent.

Notwithstanding the intensity of these events, amnesia for the episodes usually occurs. Like sleepwalking, these episodes usually arise from slow-wave sleep. Fever and CNS depressant withdrawal potentiate sleep terror episodes. Unlike nightmares, in which an elaborate dream sequence unfolds, sleep terrors may be devoid of images or contain only fragments of very brief but frighteningly vivid and sometimes static images. It is sometimes called *pavor nocturnus,* incubus, or night terror. As with other slow-wave sleep parasomnias, sleep deprivation can provoke or exacerbate sleep terrors. Psychopathology is seldom associated with sleep terrors in children; however, a history of a traumatic experience or frank psychiatric problems is often comorbid in adults with this disorder. Severity ranges from less than once per month to almost nightly occurrence (with injury to the patient or others).

CONFUSIONAL AROUSALS. ICSD-3 defines confusional arousals as a milder form of NREM sleep parasomnias. It is common in young children. The child will typically partially awaken from sleep and sit up. The child is confused, but lies back down and resumes sleep. Confusional arousals, sleepwalking, and sleep terrors likely lie on a continuum.

SLEEP-RELATED EATING DISORDER. This diagnosis is subsumed under the DSM-5 classification NREM sleep arousal disorders and specified as

"sleepwalking with sleep-related eating." In this disorder, eating may become obsessional, and the patient may eat several small meals during a night. The individual may be unaware of the activity, and weight gain can become a problem. During the recurrent sleep-related eating episodes, the individual may consume unusual foods or food combinations or may injure themselves or create a hazard while preparing food (e.g., starting a fire on the stove). They may also experience health consequences from these episodes.

REM-Related Parasomnias. Table 15-13 compares the diagnostic approaches to the REM-related parasomnias.

NIGHTMARE DISORDER. Nightmares are frightening or terrifying dreams. Sometimes called *dream anxiety attacks*, they produce sympathetic activation and ultimately awaken the dreamer. Nightmares occur in REM sleep and usually evolve from a long, complicated dream that becomes increasingly frightening. Having aroused to wakefulness, the person typically remembers the dream (in contrast to sleep terrors). Some nightmares are recurrent, and reportedly when they occur in association with posttraumatic stress disorder, they may be recollections of actual events. Common in children ages 3 to 6 years, nightmares are rare in adults. Frequent and distressing nightmares are sometimes responsible for insomnia because the individual is afraid to sleep. Most people with nightmares are free from psychiatric conditions. Traumatic events are known to induce nightmares, sometimes immediately, but at other times delayed. The nightmares can persist for many years. Several medications can provoke nightmares, including L-DOPA and β-adrenergic blockers. Withdrawal from REM suppressant medications may induce nightmares, as well. Finally, drug or alcohol abuse is associated with nightmares.

Table 15-13

Nightmare Disorder

	DSM-5	ICSD-3	ICD-10
Name	Nightmare disorder	Nightmare disorder (classified under REM-related parasomnia; see Table 15-13)	Nonorganic disorders of the sleep–wake schedule Sleep terrors Nightmares
Symptoms	Pattern of long, dysphoric, threatening, vivid dreams Dreams are recalled On awakening, quickly becomes awake and alert	Recurrent, highly dysphoric or anxiety-laden nightmares Dreams are remembered upon awakening	Sleep terrors: Nighttime episodes of terror and panic associated with motor movement and vocalization High levels of autonomic tone

			Little to no recall of the event Nightmares: Dreams associated with fear and negative emotion Intact recall of dream content
# Symptoms needed	All of the above		
Exclusion (not the result of):	Effects of a substance or medication Coexisting mental or medical disorder		Not associated with vocalization and body movement
Psychosocial impact	Marked distress and/or impairment in areas of functioning	Marked distress and/or impairment in areas of functioning	
Symptom specifiers	• **During sleep onset** • **With associated nonsleep**		

	disorder (including substance use disorder) • **With associated other medical condition** • **With associated other sleep disorder**
Severity specifiers	**Mild** (less than one episode per week) **Moderate** (one or more episodes per week, but less than nightly) **Severe** (nightly episodes)
Course specifiers	**Acute** (duration ≤1 mo) **Subacute** (1–6 mo)

Persistent (≥6 mo)		

Frequently occurring nightmares often produce a "fear of sleeping" type of insomnia. In turn, insomnia may provoke sleep deprivation, which is known to exacerbate nightmares; hence, a vicious cycle.

ICSD includes it among the REM-related sleep disorders whereas DSM-5 classifies this as a separate disorder. ICD considers this a "nonorganic disorder" of the sleep–wake schedule, along with sleep terrors. Table 15-14 compares the diagnostic approaches.

REM SLEEP BEHAVIOR DISORDER. RBD involves a failure of the patient to have atonia (sleep paralysis) during the REM stage sleep. The result is that the patient enacts his or her dreams. Under normal circumstances, the REM-related hypopolarization of α and γ motor neurons immobilizes the dreamer. Without this paralysis or with intermittent atonia, a dreamer could punch, kick, leap, while dreaming. The activity correlates with dream imagery.

Unlike sleepwalking, the individual seems unaware of the actual environment but instead is acting on the dream sensorium. Thus, a sleepwalker may calmly go to a bedroom window, open it, and step out. By contrast, a person with RBD would more likely dive through the window, thinking it is a dream-visualized lake. Patients and bed partners frequently sustain an injury, which is sometimes severe (e.g., lacerations, fractures). A wide variety of drugs and comorbid conditions can precipitate or worsen RBD.

RECURRENT ISOLATED SLEEP PARALYSIS. Sleep paralysis is, as the name implies, an inability to make voluntary movements during sleep. It becomes a parasomnia when it occurs at sleep onset or on awakening, a time when the individual is partially conscious and aware of the surroundings. This inability to move can be extremely distressing, especially when coupled with the feeling that there is an intruder in the house or when hypnagogic hallucinations are occurring. Sleep paralysis is part of the tetrad of symptoms associated with narcolepsy; however, it can occur (with or without hypnagogia) in individuals that have neither cataplexy nor excessive daytime

sleepiness. Although it is sometimes frightening, sleep paralysis is a feature of normal REM sleep, briefly intruding into wakefulness. The paralysis may last from one to several minutes.

Interestingly, the occurrence of sleep paralysis with hypnagogia may account for a variety of experiences in which the sleeper is confronted or attacked by some sort of "creature." The standard description is that the paralyzed sleeper feels a "presence" nearby, and the creature talks, attacks, or sits on the sleeper's chest and then vanishes. Whether it is called an incubus, "Old Hag," a vampire, ghost oppression (*kanashibari* in Japanese), witch riding, or an alien encounter, all these experiences have elements that are similar to descriptions of sleep paralysis. Irregular sleep, sleep deprivation, psychological stress, and shift work increase the likelihood of sleep paralysis.

Other Parasomnias

EXPLODING HEAD SYNDROME. Individuals with the parasomnia "hear" a loud imagined noise or a sense of an explosion. They experience it as inside their head as they are falling asleep or awakening. The experience can occur just once or recurrently. There is no pain associated with the noise, but the individual may be concerned that they are having a stroke or that something is very wrong. Even a single episode can trigger severe insomnia. There are no known neurologic consequences to this syndrome.

SLEEP-RELATED HALLUCINATIONS. This parasomnia typically involves visual images occurring at sleep onset (hypnagogic) or on awakening (hypnopompic) from sleep. Sometimes challenging to differentiate from dreams, they are common in patients with narcolepsy. Complex hallucinations are rare and usually happen with abrupt awakening and without remembering dreaming. Images tend to be vivid and immobile and persist for several minutes. They usually appear when turning on a light. The images can be frightening.

SLEEP ENURESIS. Sleep enuresis is a disorder in which the individual urinates during sleep while in bed. It is commonly called *bed-wetting* and has primary and secondary forms. In children, primary sleep enuresis is the continuance of bed-wetting since infancy. Secondary enuresis refers to relapse after toilet training was complete, and there was a period during which the child

remained dry. Usually, after toilet training, bed-wetting spontaneously resolves before age 6 years.

Parental primary enuresis increases the likelihood that the children will also have enuresis. A single recessive gene is suspected. Secondary enuresis in children may occur with the birth of a sibling and represent a "cry for attention." Secondary enuresis can also be associated with nocturnal seizures, sleep deprivation, and urologic anomalies. In adults with sleep-disordered breathing, sleep enuresis may occur. In most cases, embarrassment, shame, and guilt are the most substantial consequences. Nonetheless, if we do not address sleep enuresis, it may leave psychosocial scars.

PARASOMNIA DUE TO DRUG OR SUBSTANCE USE AND PARASOMNIA DUE TO MEDICAL CONDITIONS. Many drugs and substances can trigger parasomnias, particularly those agents that lighten sleep; however, alcohol is notorious for producing sleepwalking (even in individuals who have taken sleeping pills). Table 15-15 lists some medications and drugs that can worsen parasomnias.

Seizure disorder should always be on the top of a differential diagnosis list for most parasomnias. The American Academy of Sleep Medicine practice guidelines concerning the indications for polysomnography includes using sleep testing to rule out seizures when diagnosing sleep terror, sleepwalking, RBD, nightmares, and other parasomnias. Sleep-related breathing disorders are also known to trigger sleepwalking, enuresis, sleep terror, confusional arousal, and nightmares. RBD is associated with a variety of neurologic conditions, including Parkinson disease, dementia, progressive supranuclear palsy, Shy–Drager syndrome (a movement disorder with autonomic arousal symptoms), narcolepsy, and others.

Restless Legs Syndrome. RLS is an uncomfortable, subjective sensation of the limbs, usually the legs, sometimes described as a "creepy-crawly" feeling, and the irresistible urge to move the legs when at rest or while trying to fall asleep. Patients often report the sensation of ants walking on the skin and crawling feelings in their legs. It tends to be worse at night, and moving the legs or walking helps to alleviate the discomfort. Thus, as the individual is lying in bed and relaxing, he or she is disturbed by these sensations. Then he or she moves the legs and again tries to fall asleep. This cycle sometimes continues for hours and results in profound insomnia. Table 15-16 compares

the diagnostic approaches to RLS.

Table 15-15
Medications and Drugs Causing or Worsening Certain Parasomnias

REM Sleep Behavior Disorder
Biperiden
Caffeine
Monoamine oxidase inhibitors (MAOIs)
Selegiline
Serotonin agonists
Tricyclic antidepressants
Venlafaxine
Withdrawal syndromes
   Alcohol
   Meprobamate
   Pentazocine
   Nitrazepam

Nightmares
Alcohol abuse or withdrawal
Drug-induced REM sleep rebound (e.g., withdrawal from REM-suppressing drugs such as methamphetamine)
l-DOPA
β-Blockers

A variety of medical conditions can cause secondary RLS, and we list these in Table 15-17. A detailed history and physical examination are essential parts of the RLS workup. Also, we should check a ferritin level in every patient with symptoms consistent with RLS.

Periodic Limb Movement Disorder. Periodic limb movement disorder (PLMD), previously called *nocturnal myoclonus,* involves brief, stereotypic, repetitive, nonepileptiform movements of the limbs, usually the legs. It

occurs primarily in NREM sleep and involves an extension of the big toe. A partial flexion of the ankle, knee, and hip may also occur. These movements range from 0.5 to 5 seconds in duration and occur every 20 to 40 seconds. The leg movements are frequently associated with brief arousals from sleep and, as a result, can (but do not always) disturb sleep architecture. The prevalence of PLMD increases with aging and can occur in association with folate deficiency, renal disease, anemia, and the use of antidepressants.

Sleep-Related Leg Cramps. Nocturnal leg cramps are much like leg cramps that occur during wakefulness. They usually affect the calf and are painful muscle contractions. The pain awakens the sleeper and thereby disrupts sleep. Metabolic disorders, mineral deficiencies, electrolytic imbalances, diabetes, and pregnancy are known precipitators. The reason that some individuals have repeated leg cramps during sleep and not during the day is not known.

Sleep-Related Bruxism. Sleep-related bruxism occurs when an individual grinds or clenches the teeth during sleep. Formerly classified as a parasomnia, sleep bruxism can produce abnormal wear and damage to teeth, provoke tooth and jaw pain, or make loud, unpleasant sounds that disturb the bed partner. Sometimes atypical facial pain and headache also result. More than 85 percent of the population may brux at one time or another; however, it is clinically significant in only about 5 percent. Teeth grinding occurs in any sleep stage but is most common at the transition to sleep, in stage 2 sleep, and during REM sleep. Some evidence indicates that teeth grinding during REM sleep is more commonly associated with dental wear or damage. Sleep bruxism does not appear to be exacerbated by dental malocclusion. It worsens during periods of stress. Researchers studying sleep bruxism have found that many patients seem to have less frequent teeth grinding when sleeping in the laboratory; therefore, we may need repeat studies to document the disorder. By contrast, bruxism frequently appears on polysomnographic recordings made for other purposes. Sleep bruxism may occur secondary to sleep-related breathing disorders, the use of psychostimulants (e.g., amphetamine, cocaine), alcohol ingestion, and treatment with some SSRIs. Sleep bruxism can infrequently occur (monthly), regularly (weekly), or frequently (nightly). We judge the severity by considering the degree of sleep

disruption, consequent pain, and dental damage.

Table 15-16
Restless Legs Syndrome

	DSM-5	ICSD-3	ICD-10
Name	Restless legs syndrome	Restless legs syndrome	Other specified extrapyramidal and movement disorders **Restless legs syndrome**
Duration	≥3×/wk for ≥3 mo		
Symptoms	Urge to move legs Worse at night Urge relieved by movement	Urge to move legs Uncomfortable sensations occurring during rest/inactivity At least partially relieved by movement Tend to have circadian pattern (occurring primarily at night)	Experiencing a strong urge to move legs to relieve discomfort often occurs while lying down or sitting and tends to be worse at night
# Symptoms needed	All the above	All the above	

Exclusion (not the result of):	Akathisia Effects of a substance or medication Another mental disorder or medical condition Behavioral condition (i.e., habitual movements)	
Psychosocial impact	Marked distress and/or impairment in areas of functioning present	Marked distress and/or impairment in areas of functioning present

Sleep-Related Rhythmic Movement Disorder. This sleep disorder consists of repetitive, rhythmic movements, usually involving the head and neck. Most often occurring at the transition from wakefulness to sleep, this movement disorder may also continue during light sleep. Formerly classified as a parasomnia, sleep-related rhythmic movement disorder has many names, including *jactatio capitis nocturna,* headbanging, head rolling, body rocking, and *rhythmie du sommeil.* Most infants body rock. Some clinicians believe that body rocking develops from the soothing effect of vestibular stimulation. If the rhythmic movement persists into childhood, the risk of injury increases. This is particularly true if the movement includes headbanging. The male to female ratio is 4:1. Severity ranges from less than one episode weekly to nightly episodes producing injury.

Table 15-17
Medical Disorders That Can Cause Secondary Restless Legs Syndrome

COPD
Diabetes
Fibromyalgia
Iron and folic acid deficiency anemias
Neuropathies
Rheumatoid arthritis
Thyroid diseases
Uremia

Benign Sleep Myoclonus of Infancy. Previously called benign neonatal sleep myoclonus, this disorder is characterized by asynchronous jerking of limbs and trunk during quiet sleep in neonates. This benign, apparently rare, parasomnia usually begins within the first week of life and may last a few days or several months. It does not require any treatment and should resolve with time.

Propriospinal Myoclonus at Sleep Onset. Propriospinal myoclonus at sleep onset is a spinal cord–mediated movement disorder, sometimes associated with spinal cord lesions. Movements appear during times of wakeful relaxation and may interfere with sleep onset. They start in the abdominal and truncal muscles and then progress to the neck and proximal muscles of the limbs.

Sleep-Related Movement Disorder due to Medication or Substance Use and Sleep-Related Movement Disorder due to Medical Condition. A variety of medications, substances, and comorbid conditions can produce or exacerbate sleep-related movement disorders. Table 15-18 lists some example medications. Neurologic diseases that are associated with daytime movement disorders can also be associated with sleep-related movement disorders. Stress, anxiety, and sleep deprivation may contribute to bruxism.

Table 15-18
Medications Causing Sleep-Related Movement Disorders

Antidepressants (including most tricyclics and SSRIs)
Antiemetics
Antihistamines
Antipsychotics (restless legs symptoms, periodic limb movement disorder)
Calcium channel blockers
Lithium
Stimulants (rhythmic movement disorders, bruxism)

Isolated Symptoms and Normal Variants

Sleep Talking. As the name implies, sleep talking in classic form involves unconscious speech during sleep. Unless it annoys the bed partner, it is seldom recognized. Fever, stress, or talking with the sleeper can all induce the behavior. Somniloquy may accompany sleep terror, sleepwalking, confusional arousals, OSAs, and RBD.

Sleep Starts (Hypnic Jerks). Sleep starts are sudden, brief muscle contractions that occur at the transition between wakefulness and sleep in 60 to 70 percent of adults. The contractions commonly involve the legs; however, sometimes there is movement in the arms and head. Sometimes called a "hypnic jerk," it is usually benign. The sleep start, however, can interfere with the ability to fall asleep and may be accompanied by sensations of falling, a hallucinated flash of light, or a loud crackling sound. In severe cases, the sleep start produces profound sleep-onset insomnia.

CLINICAL TOOLS IN SLEEP MEDICINE

Clinical Interview

A careful and thorough clinical interview is one of the most informative parts of a workup for sleep disorders. The habitual bedtime and arising times for both weekdays and weekends, the frequency, duration, and restorative nature

of naps, and overall level of sleepiness are good places to begin. Specific sleep problems relating to difficulty initiating and maintaining sleep are informative, including whether there is rumination at bedtime, fear of not being able to sleep, or excessive worry when attempting to sleep. We should assess for movements, including leg movement, leg sensations, leg cramps, teeth grinding, and dream enactments (with or without injury). We should also review for morning headaches, morning dry mouth, nocturnal reflux, hyperhidrosis (excess sweating), nocturia, enuresis, nocturnal tongue biting, nightmares, sleep terrors, and other sleep-related problems. In some cases, it can be crucial to ask about the presence of family pets and whether they sleep in the bedroom (or bed). A sleep history questionnaire is often helpful in diagnosing a patient's sleep disorder (Table 15-19).

Clinical Tests

Polysomnography. Polysomnography is the continuous, attended, comprehensive recording of the physiologic changes that occur during sleep. A polysomnogram is typically recorded at night and lasts between 6 and 8 hours. Brain wave activity, eye movements, submentalis electromyography activity, nasal–oral airflow, nasal pressure, respiratory effort, oxyhemoglobin saturation, heart rhythm, and leg movements during sleep are measured. Usually, the laboratory records body position and snoring sounds. Brain wave activity, eye movements, and submentalis electromyogram are essential for identifying sleep stages and CNS arousals. Muscle tension and movements subside with deeper sleep and can also be useful in the diagnosis of PLMD and RLS. Nasal airflow, respiratory effort, and oxyhemoglobin saturation are instrumental in diagnosing sleep apnea and other sleep-related breathing disorders.

Table 15-20 lists the most common reasons for ordering polysomnography. A sleep study is not needed to diagnose RLS.

Table 15-21 lists standard polysomnographic measures.

Home Sleep Testing. Home sleep testing involves recording a limited number of cardiopulmonary parameters to assess patients for sleep-related breathing disorders. Home sleep testing is much less expensive than polysomnography. The test can record airflow, respiratory effort, heart

rhythm, snoring sounds, and oximetry. Several devices are commercially available that are capable of detecting sleep apnea in patients with moderate to severe pathophysiology. Negative studies are problematic because home sleep testing is less sensitive than full laboratory polysomnography. Patients with negative tests, notwithstanding obvious symptoms or comorbidity, should be scheduled for laboratory polysomnography. Also, home sleep testing does not check for the full spectrum of sleep disorders; therefore, the presence of residual symptoms after a breathing disorder is diagnosed in this manner and treated indicates a need for careful follow-up.

Multiple Sleep Latency Test. The multiple sleep latency test (MSLT) is essential for the workup of narcolepsy. Every 2 hours, beginning 2 hours after morning awakening, the patient is provided with 20-minute nap opportunities and instructed not to resist falling asleep. During sleep, the laboratory records electroencephalographic, electrooculographic, and submentalis electromyography activity to determine the sleep stage. The latency to sleep helps assess hypersomnolence, and the appearance of REM sleep on two or more nap opportunities confirms narcolepsy (or on one nap if the previous night's polysomnography revealed REM sleep within 15 minutes of sleep onset). If the patient falls asleep on a given nap opportunity, the laboratory will wake the patient 15 minutes after initial sleep onset. If the patient does not fall asleep after 20 minutes, the laboratory will terminate the session. The laboratory gives the patient five nap opportunities during 2-hour intervals across the day.

Maintenance of Wakefulness Test. Similar to the MSLT, the maintenance of wakefulness test (MWT) provides 40-minute test sessions at 2-hour intervals across the day. However, in this test, the laboratory instructs the patient to try to remain awake. This technique is used to assess treatment outcomes and is sometimes part of "fit for duty" testing. Patients are recorded in a darkened room while sitting in a comfortable chair or a bed with a bolster pillow. The first epoch of stage 2, 3, or 4 sleep or REM or three consecutive epochs of stage 1 mark unequivocal sleep onset. Falling asleep on MWT indicates some level of sleepiness. Any sleep latency of fewer than 8 minutes is abnormal. Sleep latency ranging from 8 to 40 minutes is of unknown significance.

Actigraphy. An actigraph is a device that measures and records movement. It is usually worn on the wrist (like a watch) and is a rough measure of the sleep–wake cycle. Depending on the model and the settings, it can make continuous recordings for days or weeks. It can be especially useful for assessing insomnia, circadian rhythm disorders, movement disorders, and an assortment of rare events.

Common Test Findings in Sleep–Wake Disorders

Hypersomnolence Disorder. The EEG sleep pattern is essentially the same as that found in healthy individuals who are sleep deprived (Fig. 15-2). Unlike a sleep-deprived individual, the sleep pattern continues in this profile even after several nights of extended sleep. Also, we may see elevated slow-wave sleep.

Narcolepsy. When the diagnosis is not clinically apparent, a nighttime polysomnographic recording reveals a characteristic sleep-onset REM period (Fig. 15-3). A test of daytime MSLT shows rapid sleep onset and usually one or more sleep-onset REM periods.

Table 15-20
Indications for Polysomnography

Common Reasons

Diagnosis of sleep-related breathing disorders

Positive airway pressure (PAP) titration and assessment of treatment efficacy

Evaluation of sleep-related behaviors that are violent or may potentially harm the patient or bed partner

Differentiating narcolepsy from other hypersomnolence disorders

Differentiating parasomnias from nocturnal seizures

Other Possible Uses

Diagnose atypical parasomnias
Sleep-related problems secondary to neuromuscular disorders
Periodic limb movement disorder
Arousals secondary to seizure disorder
Excessive daytime sleepiness
Waking up gasping or choking
Narcolepsy (to assess sleep quality and quantity prior to a multiple sleep latency test)

Obstructive Sleep Apnea. On the polysomnogram, episodes of OSA appear as multiple periods of at least 10 seconds' duration in which nasal and oral airflow ceases either wholly or partially. Meanwhile, the abdominal and chest expansion leads indicate the continuing efforts of the diaphragm and accessory muscles of respiration to move air through the obstruction (Fig. 15-4). The arterial oxygen saturation drops, and often we see bradycardia, along with possible arrhythmias, such as premature ventricular contractions. In the end, an arousal reflex takes place, seen as a waking signal, and possibly as a motor artifact on the EEG channels. At this moment, sometimes called the *breakthrough,* the patient can make brief restless movements in bed.

**Table 15-21
Common Polysomnographic Measures**

Sleep latency: Period of time from turning out the lights until the appearance of stage 2 sleep

Early morning awakening: Time of being continuously awake from the last stage of the sleep until the end of the sleep record (usually at 7 am)

Sleep efficiency: Total sleep time or total time of the sleep record × 100

Apnea index: Number of apneas longer than 10 s/h of sleep

Nocturnal myoclonus index: Number of periodic leg movements per hour

Rapid eye movement (REM) latency: Period of time from the onset of sleep until the first REM period of the night

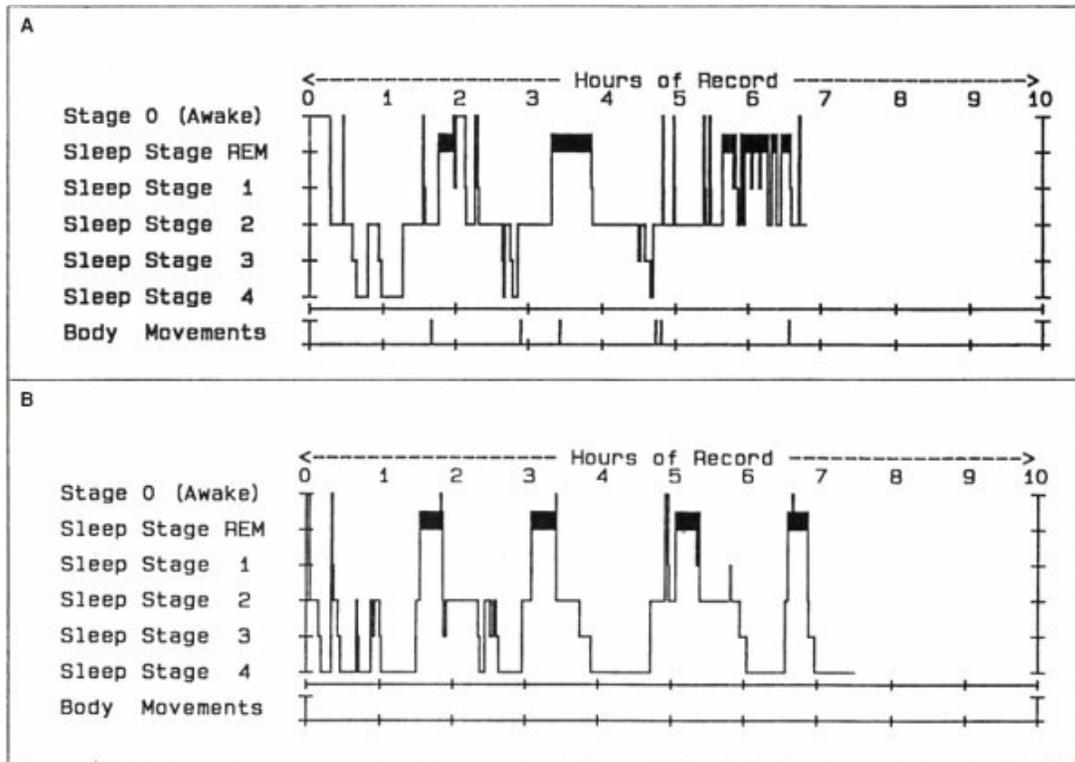
Sleep-onset REM period: REM sleep within the first 10 min of sleep


FIGURE 15-2

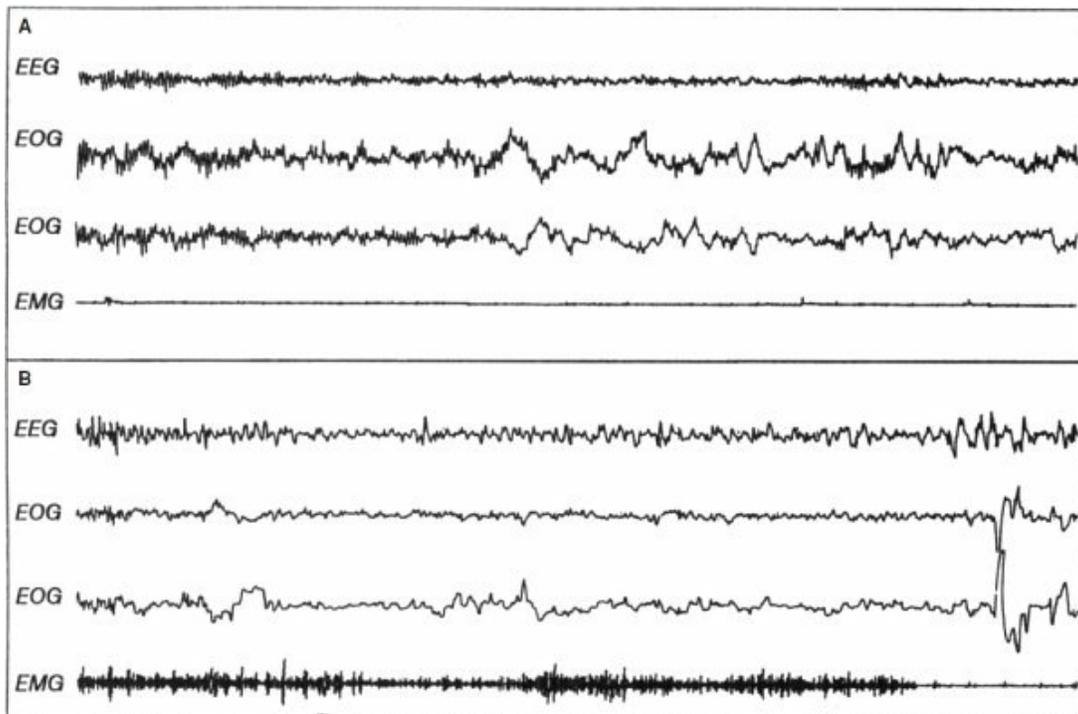
Sleep stage histograms comparing a normal sleep profile with that of a patient with hypersomnolence. **Panel A** illustrates the sleep pattern recorded in a healthy young adult. His sleep was interrupted several times by awakenings associated with other concurrent laboratory procedures; however, all parameters were within normal limits. **Panel B** depicts the sleep pattern of a patient with severe daytime sleepiness. The patient did not have narcolepsy or apnea. In the laboratory, sleep onset was rapid, sleep continued virtually without interruption, and he was extremely difficult to arouse. This recording was terminated after 7.5 hours to begin daytime testing; however, the patient's sleep revealed little indication of progressing toward a lighter state. In contrast to the normal sleep pattern, slow-wave sleep duration was elevated and it continued to emerge in alternation with REM sleep throughout the night. The patient awoke feeling unrefreshed and not satisfied with his sleep.


FIGURE 15-3
Polysomnographic tracing comparing normal sleep onset with that of a patient with narcolepsy. Each panel illustrates approximately 30 seconds of polysomnographic recording beginning with relaxed wakefulness. **Panel A** (normal sleep progression) shows a reduction of EEG α activity and development of slow rolling eye movements. **Panel B** shows the normally expected abatement of EEG α activity associated with increased θ activity and the appearance of a few slow eye movements. However, within 25 seconds (far right of figure) a swift loss of muscle tone occurs accompanied by rapid eye movements. This appearance of sleep-onset REM sleep (SOREM) characterizes narcolepsy and is part of the diagnostic criteria.

Central Sleep Apnea. The polysomnographic features of CSA are similar to those of OSA. However, during the periods of apnea, cessation of respiratory effort is seen in the abdominal and chest expansion leads. In Cheyne–Stokes breathing, polysomnography reveals five or more central apnea and hypopnea episodes per hour of sleep. In CSA, due to a medical disorder without Cheyne–Stokes breathing, diagnostic criteria require a polysomnographically verified rate of 5 or more central apneas and hypopneas per hour of sleep. Also, CSA due to medication or substance requires five or more central apneas per hour.

Sleep-Related Hypoventilation. Polysomnography demonstrates either episodes with elevated CO_2 levels and decreased respirations or, if not

monitoring CO_2, episodes of persistently low oxyhemoglobin levels that are not provoked by apnea or hypopnea.

Parasomnias. Sleep studies help to develop a differential diagnosis and rule out that the unusual behavior is secondary to a seizure, sleep-related breathing disorder, or another sleep disorder. Figures 15-5 to 15-7 give examples of polysomnograms for sleep terrors, RLS, and sleep-related bruxism.

DIFFERENTIAL DIAGNOSIS

In general, the differential diagnosis of sleep–wake disorders should include other individual sleep–wake disorders, psychiatric disorders, medical conditions, medications and substance use, and normal variants.

Insomnia Disorder

Many psychiatric disorders can cause a person to experience insomnia. For example, MDD, bipolar disorder, and PTSD can all present with sleep disruption. Many medications and substances also affect sleep, some of which we listed in Table 15-7. Other sleep–wake disorders should also be considered, including circadian rhythm sleep–wake disorder, RLS, sleep-related breathing disorders, narcolepsy, and parasomnias. Finally, one should consider whether the sleep pattern is a normal variant in the population (e.g., a "short sleeper") or is occurring in the context of an acute stressor.

Hypersomnolence Disorder

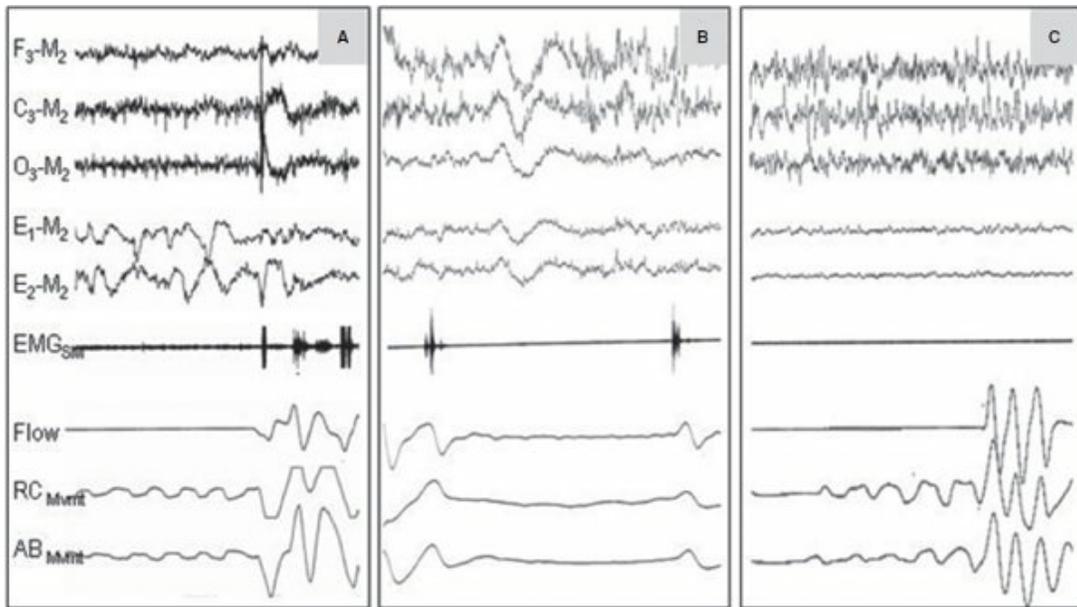
Psychiatric disorders associated with increased sleep or fatigue, such as MDD or bipolar depression, should be considered part of the differential diagnosis. Certain medications or substances can also cause sedation, such as sedative–hypnotics and opioids. Other sleep–wake disorders should be considered, including circadian rhythm sleep–wake disorder, sleep-related breathing disorders, and parasomnias. Also, poor sleep quality can lead to excessive daytime sleepiness, and there are some persons for whom it is a normal variant to require more sleep (e.g., "long sleepers").


FIGURE 15-4

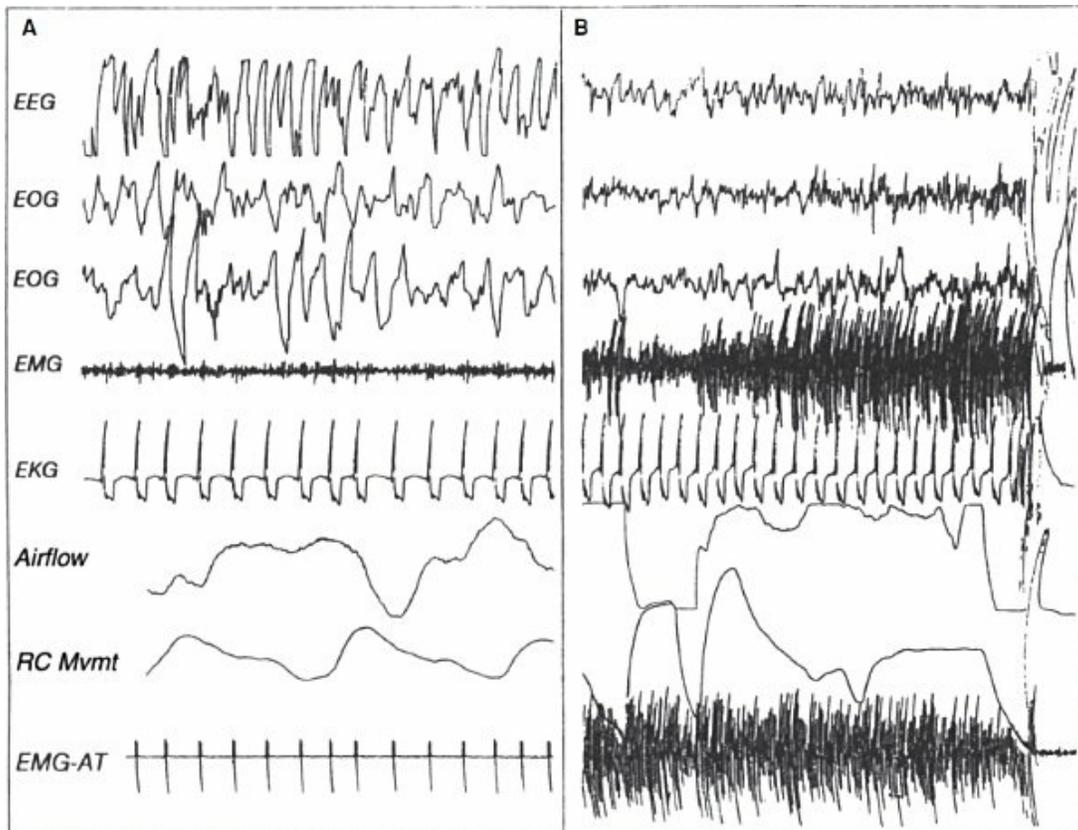
Polysomnographic tracings illustrating sleep apnea episodes. **Panel A** illustrates an obstructive sleep apnea, **Panel B** shows a central sleep apnea, and **Panel C** depicts a mixed sleep apnea. Note the presence of respiratory effort (rib cage and abdominal movement), notwithstanding cessation of airflow, throughout the obstructive apnea and during the latter portion of the mixed apnea. By contrast, respiratory effort is absent during the flow cessation throughout the central apnea and during the early portion of the mixed apnea. Notation: F_3 (left frontal scalp derivation); M_2 (right mastoid electrode location); C_3 (left central scalp derivation); O_3 (left occipital scalp derivation); E_1 (left outer canthus eye electrode location); E_2 (right outer canthus eye electrode location); EMG_{SM} (surface electrode electromyogram from submentalis muscle); Flow (airflow measured with nasal–nasal–oral thermistors); RC Mvmt (rib cage movement measured with inductive plethysmography); AB Mvmt (abdominal movement measured with inductive plethysmography). (From Hirshkowitz M, Sharafkhaneh A. Diagnostic assessment methods in adults. In: Kryger MH, Avidan AY, Berry RB, eds. *Atlas of Clinical Sleep Medicine*. 2nd ed. Elsevier Saunders: Philadelphia, PA; 2014:378.)


FIGURE 15-5

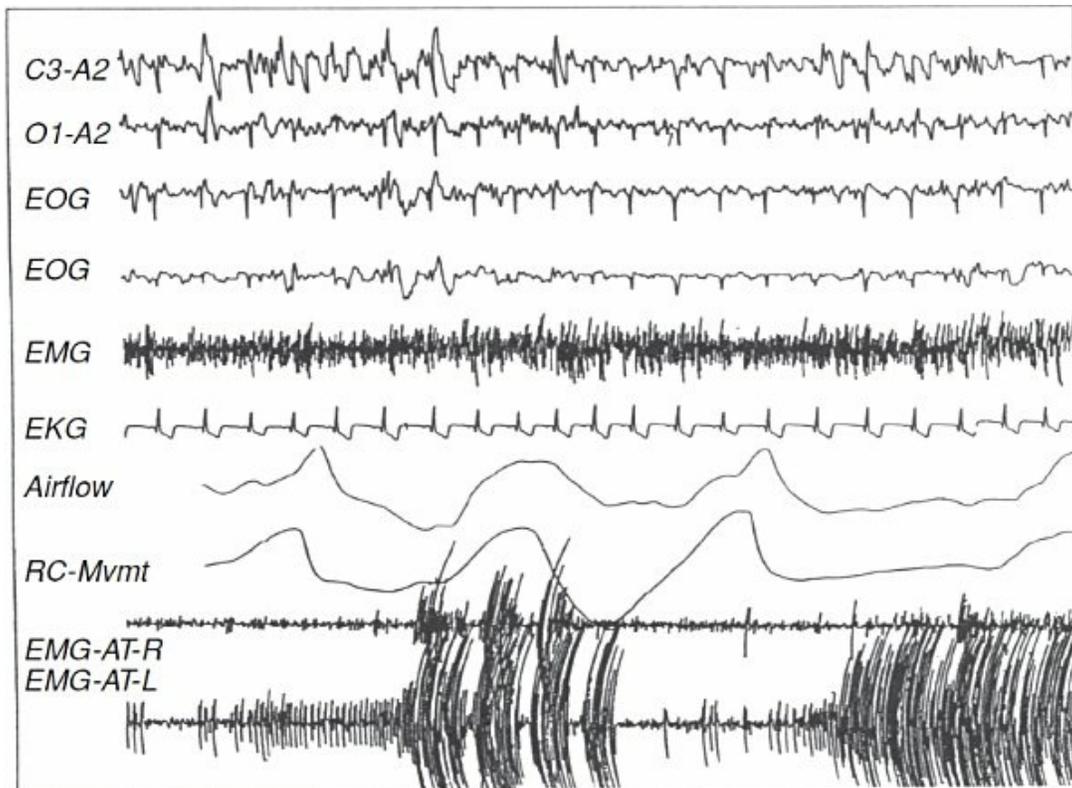
Polysomnographic tracing illustrating a sleep terror. **Panel A** shows approximately 14 seconds of tracing occurring immediately before the sleep terror. Prominent EEG slow-wave activity and other characteristics of stage 4 sleep are seen. **Panel B** shows the awakening, accompanied by tachycardia and movement. EEG activity is ambiguous and the patient eventually disconnected his electrodes as he thrashed about in bed (visible at far right of figure). Although the patient was screaming and greatly agitated, there was no report of dreaming. In the morning, there was little recollection of anything having occurred during the night.


FIGURE 15-6

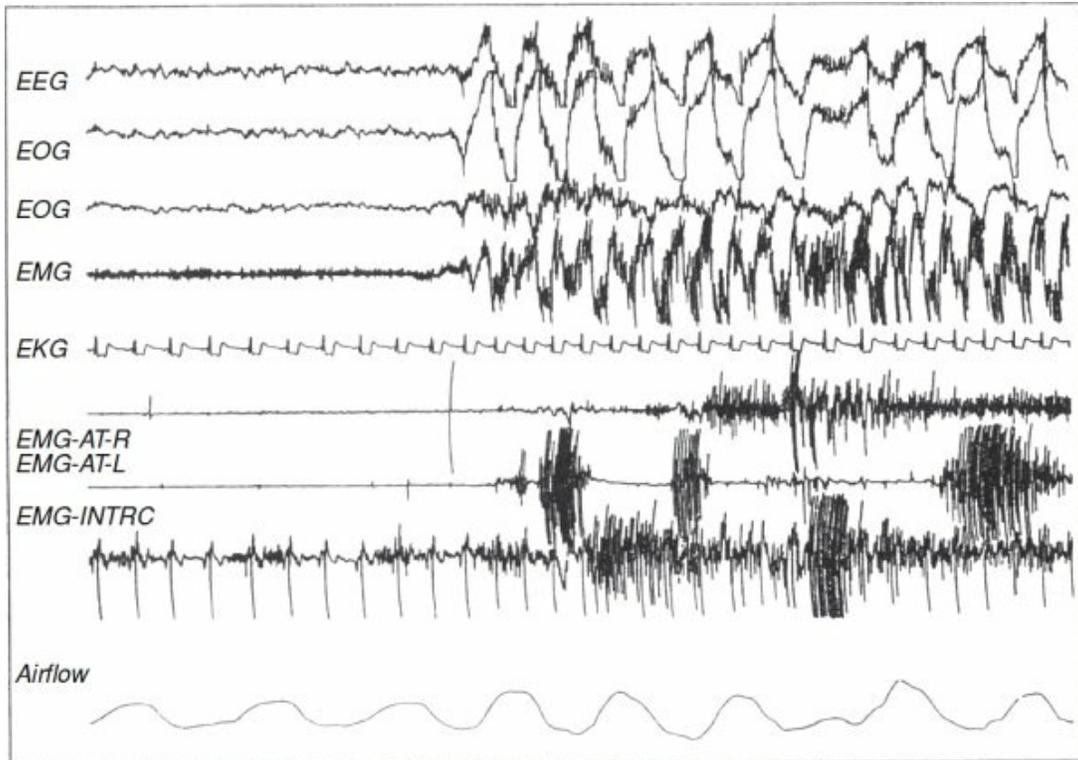
Restless legs syndrome. This patient presented with complaints of uncomfortable, crawling sensations in the legs when trying to fall asleep. Patients commonly report an urge to move the leg in order to dispel the sensation. This figure shows a bilateral pattern of leg EMG activity; however, the discharge is more pronounced in the left anterior tibialis (EMG-AT-L) than the right (EMG-AT-R). This pattern continued for more than an hour as the patient attempted to fall asleep; note that the sharp activity in central and occipital EEG (C3-A2 and O1-A2, respectively) and EOG is EKG artifact and not an EEG abnormality.


FIGURE 15-7
Polysomnographic tracing showing sleep-related bruxism. This figure showing approximately 25 seconds of tracing was obtained from a patient during an episode of bruxism. Bruxism can occur during any stage of sleep or wakefulness. The interference pattern of EEG-EOG-EMG channels is typical and reflects the rhythmic jaw movement and grinding of the teeth. This patient had many such episodes, some that caused awakening. Readily observable tooth damage and jaw pain were noted.

**Table 15-22
Medical Disorders Causing Cataplexy**

Disorders affecting the hypothalamus
   Tumors
   Sarcoidosis
   Multiple sclerosis plaques
Paraneoplastic syndrome
Neimann–Pick type C disease
Coffin–Lowry syndrome

Narcolepsy

The differential diagnosis of narcolepsy includes many of the same disorders as the differential diagnosis of hypersomnolence disorder. Also, cataplexy can be confused for seizures or neurologic movement disorders (e.g., chorea). Many disorders can precipitate cataplexy, and we list some of the more common in Table 15-22. All of these disorders would preclude a diagnosis of narcolepsy. Cataplexy is usually absent in narcolepsy associated with multiple sclerosis, myotonic dystrophy, Prader–Willi syndrome, Parkinson disease, and multisystem atrophy.

Sleep-Related Breathing Disorders

The differential diagnosis of sleep-related breathing disorders includes many of the same disorders as the differential diagnosis of insomnia and hypersomnolence disorders, given the clinical presentation of fatigue and daytime sleepiness. Other possible conditions include panic attacks and attention-deficit/hyperactivity disorder (as repeated apneic episodes may lead to problems with focus, attention, and school- or job-related performance).

Circadian Rhythm Sleep–Wake Disorders

The differential diagnosis of circadian rhythm sleep–wake disorders includes insomnia disorder, other sleep–wake disorders, and mood disorders. One should also consider the possibility that the sleep pattern represents a normal variant.

Parasomnias and Sleep-Related Movement Disorders

The differential diagnosis of parasomnias can be complicated and should include other individual parasomnias, sleep-related breathing disorders, nocturnal seizures, panic attacks, other sleep–wake disorders, amnestic and dissociative syndromes, and numerous medical conditions. The differential diagnosis of RLS includes multiple medical conditions, such as arthritis, neuropathy, positional ischemia, and peripheral artery disease, to name a few, while the differential diagnosis of sleep-related bruxism should include nocturnal seizures.

COMORBIDITY

Insomnia Disorder

Several psychiatric disorders are often comorbid with insomnia. We list some common ones in Table 15-23. Nearly 90 percent of patients with MDD have insomnia. Of the most significant concern, insomnia is an independent risk factor for suicide in patients with MDD. Insomnia also predicts who will develop posttraumatic stress disorder following a trauma. For bipolar patients, lack of sleep may precipitate a manic episode. Patients with schizophrenia may deny having slept despite objective measures showing normal sleep.

Hypersomnolence Disorder

Many disorders also occur with hypersomnolence disorder, and we list some of these in Table 15-23. Medication use disorders are also common, particularly the stimulants, as the individual attempts to stay awake.

Narcolepsy

Narcolepsy is associated with psychiatric disorders in general, as well as many medical disorders. We list some of these in Table 15-23.

Sleep-Related Breathing Disorders

Table 15-23 lists several disorders associated with sleep-related breathing disorders. The section on diagnosis discusses conditions associated with central sleep apnea and sleep-related hypoventilation.

Circadian Rhythm Sleep–Wake Disorders

The circadian rhythm sleep–wake disorders can be associated with psychiatric and medical comorbidities; we list some of these in Table 15-23. The shift work type is especially associated with many psychiatric and medical disorders.

Parasomnias and Sleep-Related Movement Disorders

Each parasomnia has its own set of common comorbid diagnoses, and we list some examples in Table 15-23. Many individuals who present with RBD will go on to develop a neurodegenerative disorder.

TREATMENT APPROACH

Insomnia

Pharmacologic Treatment. For many years, benzodiazepines were the most commonly prescribed sedative–hypnotic medications for treating insomnia. Other benzodiazepine-receptor agonists (e.g., zolpidem and similar drugs) then emerged as an option to treat insomnia. The subsequent development of a low-dose antihistamine (doxepin), a melatonin receptor agonist (ramelteon), and an orexin antagonist (suvorexant) have more recently augmented the armamentarium of medications approved for treating insomnia. However, unapproved off-label (and not recommended) use of sedating antidepressants is commonplace. Additionally, a variety of over-the-counter (OTC) sleep aids is available. Nonprescription formulas include sedating antihistamines, protein precursors, and other substances. L-tryptophan was trendy and readily available at health food stores until an outbreak of eosinophilia led to pulling it off the shelves. However, the cause was a single manufacturer, and L-tryptophan subsequently became available OTC again. Melatonin is the leader among self-administered food additives believed by some to alleviate sleeplessness. Low-dose melatonin can improve sleep when used to align or reentrain the circadian rhythm with the desired sleep–wake schedule.

> **Table 15-23**
> **Disorders That Are Commonly Comorbid with Various Sleep Disorders**

Insomnia Disorder
Bipolar disorder
Generalized anxiety disorder
Major depressive disorder
Posttraumatic stress disorder
Schizophrenia

Hypersomnolence Disorder
Bipolar disorder

Depressive disorders (particularly seasonal depression)
Neurodegenerative disorders
Substance use disorders (stimulants)

Narcolepsy
Anxiety
Depressive disorders
Obstructive sleep apnea
Headache
Hyperlipidemia
Hypertension
Obesity
Peripheral neuropathy
Thyroid disease, other endocrinopathies

Sleep-Related Breathing Disorders
Anxiety disorders
Dementia
Mood disorders
Post-traumatic stress disorder
Psychotic disorders
Cardiovascular disease
Diabetes mellitus
Heart failure
Hypertension
Obesity

Circadian Rhythm Sleep-Wake Disorders
Depression
Neurodegenerative disorders
Neurodevelopmental disorders
Personality disorder
Somatic symptom disorders
Blindness

Diabetes mellitus
Gastrointestinal disease
Substance use disorders

Parasomnias and Sleep-Related Movement Disorders
Sleepwalking
  Obsessive compulsive disorder
  Major depression
Nightmare disorder
  Posttraumatic stress disorder
  Acute stress disorder
  Schizophrenia
  Anxiety disorders
  Personality disorders
  Bereavement
  Pain
  Neurodegenerative disorders
  Cardiovascular disease
REM sleep behavior disorder
  Narcolepsy
  Neurodegenerative disorders
Restless legs syndrome
  Depression
  Anxiety
  Attentional disorders
  Iron deficiency

Drug manufacturers must rigorously test prescription medications in clinical trials; therefore, they hold an advantage over the virtually untested OTCs. Medication must be proven safe and effective to become FDA approved.

Most hypnotic medications are approved for short-, not long-term use. Exceptions include zolpidem-modified release, eszopiclone, and ramelteon, which the FDA approved for long-term therapy. When properly used, hypnotics can provide immediate and adequate relief from sleeplessness.

Insomnia, however, usually returns upon discontinuation of dosing.

The clinical practice guideline from the American Academy of Sleep Medicine recommends the use of suvorexant, eszopiclone, zaleplon, zolpidem, triazolam, temazepam, ramelteon, and doxepin for the treatment of insomnia (with specific agents having different indications for sleep-onset or sleep-maintenance insomnia). They recommend against the use of trazodone, tiagabine, diphenhydramine, melatonin, tryptophan, and valerian for insomnia treatment.

Cognitive-Behavioral Therapy for Insomnia. Cognitive-behavioral therapy for insomnia (CBTi), as a treatment modality, uses a combination of behavioral and cognitive techniques to overcome dysfunctional sleep behaviors, misperceptions, and distorted, disruptive thoughts about sleep. Behavioral techniques include universal sleep hygiene, stimulus control therapy, sleep restriction therapy, relaxation therapies, and biofeedback.

Studies repeatedly show significant, sustained improvement in sleep symptoms, including number and duration of awakenings and sleep latency, from CBTi. Short-term benefits are similar to that of medication, but CBTi tends to have lasting benefits, even 36 months after treatment. With the cessation of the medication, insomnia frequently returns and is sometimes accompanied by rebound insomnia. CBTi has no apparent adverse effects. There are no established "best practice" guidelines for length or quantity of sessions. CBTi, however, is not without limitations. Most data do not compare the efficacy of the individual components of CBTi. However, sleep hygiene education alone produces an insignificant effect on sleep. Intuitively, the multicomponent approach addresses many of the variables contributing to insomnia. Other limitations of CBTi include lack of or unavailability of trained specialists, cost of sessions, and noncoverage by insurance carriers.

The effects of CBTi take longer to emerge than the effects of medications. Usually, when patients finally come for treatment of their insomnia, they are desperate. It is challenging to convince them to try a therapy that may take several weeks before it will provide relief. Furthermore, patients do not assume a passive role in this type of therapy; they must be active participants. Many individuals not only want a "quick fix," but they also want to undergo a procedure or have something administered rather than be involved in the therapeutic process. For optimal CBTi, patients must commit to come to

multiple sessions and also be open to the idea that modifying thoughts and behaviors about sleep can improve the symptoms of insomnia.

Although firmly focused on cognitive and behavioral issues, it helps to extend CBT just slightly into the psychodynamic sphere. For some patients with long-standing difficulty sleeping, being an insomniac becomes an essential part of their identity. There may be primary or secondary gain to such identification. It is the negative emotional response (i.e., anger at the inability to control one's sleep, feeling like a failure because one cannot sleep) to insomnia that contributes to its chronicity. In general, these individuals tend to internalize rather than express emotion, feel a heightened need for control, experience interpersonal difficulties and have significant discontent with past events. For this subset of people, neglecting the emotional response can limit the response to treatment and cause a relapse. The clinician will be better able to intercept barriers to treatment when they attune themselves to a patient's tendency to view something as a failure rather than a challenge.

Universal Sleep Hygiene. A patient's lifestyle can lead to a sleep disturbance. We usually call this *inadequate sleep hygiene,* referring to a problem in following generally accepted practices to aid sleep. These include, for instance, keeping regular hours of bedtime and arousal, avoiding excessive caffeine, not eating heavy meals before bedtime, and getting adequate exercise. Many behaviors can interfere with sleep and may do so by increasing nervous system arousal near bedtime or by altering circadian rhythms.

The focus of universal sleep hygiene is on modifiable environmental and lifestyle components that may interfere with sleep, as well as behaviors that may improve sleep. Because some of these behaviors are difficult to change, we should concentrate on only one or two items, chosen in collaboration with the patient, to address. The patient then has the best chance at a successful intervention. We list some sleep-enhancing directives in Table 15-24. Often a few simple alterations in a patient's habits or sleep environment are useful. The clinician, however, needs to spend time reviewing both the patient's routine and its irregularity. In some respects, the essence of insomnia is its variability. The day-to-day changes in behavior and the changing severity of sleeplessness can obscure the factors responsible for the problem. A carefully

explained program of sleep hygiene, with follow-up, represents a reasonably inexpensive intervention. Furthermore, improving sleep habits can enhance sleep, even when the primary cause of insomnia is physical. However, sleep hygiene education does not appear to be as effective as CBTi.

Stimulus Control Therapy. Stimulus control therapy is a deconditioning paradigm that aims to break the cycle of problems commonly associated with difficulty initiating sleep. By attempting to undo conditioning that undermines sleep, stimulus control therapy helps reduce both primary and reactive factors involved in insomnia. The rules attempt to enhance stimulus cues for sleeping and diminish associations with sleeplessness. The instructions are simple; however, the patient must consistently follow them. We list an example of these instructions in Table 15-25. Stimulus control therapy does work; however, we might not see results for weeks or even a month. If continually practiced, the bouts of insomnia lessen in both frequency and severity.

Sleep Restriction Therapy. Sleep restriction therapy is a strategy designed to increase sleep efficiency by decreasing the amount of time spent awake while lying in bed. This therapy targets explicitly those patients who lie awake in bed, unable to sleep. Restricting time in bed can help to consolidate sleep. If the patient reports sleeping only 5 hours of an 8-hour scheduled time in bed, reduce the time in bed. It is advised, however, not to reduce bedtime to less than 4 hours per night and to warn the patient about the hazards of daytime sleepiness. Sleep at other times during the day must be avoided, except in the elderly, who may take a 30-minute nap. The clinician then monitors sleep efficiency (time asleep as a percentage of the time in bed). When sleep efficiency reaches 85 percent (averaged over five nights), we should increase the time in bed by 15 minutes. Sleep restriction therapy produces a gradual and steady decline in nocturnal wakefulness.

Table 15-24
Do's and Don'ts for Good Sleep Hygiene

	DO	DON'T
Maintain regular hours of bedtime and arising	✓	

If you are hungry, have a light snack before bedtime	✓	
Maintain a regular exercise schedule	✓	
Give yourself approximately an hour to wind down before going to bed	✓	
If you are preoccupied or worried about something at bedtime, write it down and deal with it in the morning	✓	
Keep the bedroom cool	✓	
Keep the bedroom dark	✓	
Keep the bedroom quiet	✓	
Take naps		✓
Watch the clock so you know how bad your insomnia actually is		✓
Exercise right before going to bed in order wear yourself out		✓
Watch television in bed when you cannot sleep		✓
Eat a heavy meal before bedtime to help you sleep		✓
Drink coffee in the afternoon and evening		✓
If you cannot sleep, smoke a cigarette		✓
Use alcohol to help in going to sleep		✓
Read in bed when you cannot sleep		✓
Eat in bed		✓
Exercise in bed		✓
Talk on the phone in bed		✓

Relaxation Therapy and Biofeedback. The most critical aspect of relaxation therapy is to perform it properly. Self-hypnosis, progressive

relaxation, guided imagery, and deep breathing exercises are all useful if they produce relaxation. The goal is to find the optimal technique for each patient, but not all patients need help in relaxing. *Progressive muscle relaxation* is especially useful for patients who experience muscle tension. The patients should purposefully tense (5 to 6 seconds) and then relax (20 to 30 seconds) muscle groups, beginning at the head and ending at the feet. The patient should appreciate the difference between tension and relaxation. *Guided imagery* has the patient visualize a pleasant, restful scene, engaging all of his or her senses.

Table 15-25
Stimulus Control Instructions

1. Go to bed only when sleepy to maximize success.
2. Use the bed only for sleeping. Do not watch television in bed, do not read, do not eat, and do not talk on the telephone while in bed.
3. Do not lie in bed and become frustrated if unable to sleep. After a few minutes (do not watch the clock), get up, go to another room, and do something nonarousing until sleepiness returns. Repeat as often as needed.
4. Awaken at the same time every morning (regardless of bedtime, total sleep time, or day of week) and totally avoid napping.

Table 15-26
Abdominal Breathing

1. In the supine position, the patient should breathe normally through his or her mouth or nose, whichever is more comfortable, and attend to his or her breathing pattern.
2. While maintaining that rhythm, the patient should begin to breathe more with his or her abdomen and less with his or her chest.
3. The patient should pause for a half second after each breath cycle (in and out) and evaluate the breath. How did it feel? Was it

smooth? Eventually each breath will become uniform and smooth.
4. The patient should find a place where he or she can best feel the air move in and out. Concentrate on that spot and on the air moving in and out.
5. The patient should visualize intrusive thoughts as floating away; if there are too many thoughts, stop practicing and try again later.

Breathing exercises should be practiced for at least 20 min/day for 2 weeks. Once mastered, the technique should be used once at bedtime for 30 minutes. If it does not work, the patient should try a different night again. It is essential that the technique not become associated with failure to fall asleep. Table 15-26 gives example instructions for *abdominal breathing,* an important technique. The patient should become comfortable with each step before moving on to the next.

Biofeedback provides stimulus cues for physiologic markers of relaxation and can increase self-awareness. Muscle tension in the forehead or finger temperature is measured. Finger temperature rises when a person becomes more relaxed. Patients require thorough and adequate training; merely giving them an instruction tape is not especially helpful. Techniques are ideally mastered during the day for several weeks before application to the sleep problem; the patient preferably does this outside of the bed. By the time the patient uses the techniques in bed, the skill should be automatic. Relaxation techniques readily lend themselves to being combined with sleep hygiene and stimulus control therapies. Sometimes they make for good distractions from thinking about the inability to sleep. The ruminations fuel insomnia, and if the ruminator can be distracted, then the person may sleep better.

Cognitive Therapy. This practical, validated treatment for a variety of psychiatric conditions, including major depression and generalized anxiety, has been adapted for use with insomnia. The cognitive aspect of insomnia treatment targets the negative emotional response to an appraisal of a sleep-related situation. The negative emotional response produces emotional arousal, which in turn contributes to or perpetuates insomnia. People who have maladaptive cognitions tend to exaggerate the negative consequences of insomnia: "There must be something wrong with me if I cannot fall asleep in

40 minutes." They also tend to have unrealistic expectations about their sleep requirements: "If I do not sleep 8 hours a night, then my whole day will be ruined." The first step is to identify these cognitions, then challenge their validity, and finally, substitute them with more adaptive cognitions.

DH was a 42-year-old man with a 5-year history of insomnia. He identified losing his job and the birth of a colicky baby as precipitating factors in his inability to sleep. However, even after he found a new position with better hours and pay and with the child sleeping through the night, DH continued to experience difficulty falling and staying asleep. Perpetuating factors included low back pain and a spouse with periodic limb movement disorder. He reported spending 8 to 9 hours in bed each night and sleeping only 4 to 5 hours intermittently. He watched 1 hour of television in bed before turning out the light for bedtime. He spent hours watching the minutes tick away. He did not wake feeling rested, and when his alarm went off, he was frequently already awake and had thoughts such as, "I hardly slept at all last night. I should be able to get more sleep. There must be something wrong. Great, I'll be too tired to concentrate on anything today."

Examples of maladaptive thoughts: *"I should be able to get more sleep."* This is a faulty appraisal of sleeping ability and may relate to a need for control over sleep. This need for control interferes with having a more laissez-faire attitude about a few missed hours of rest. Such thoughts can also lead to feelings of frustration and anger. *"Great, I'll be too tired to concentrate on anything today."* This is a misattribution of daytime impairment due to poor sleep. DH was also magnifying the negative and discounting the positive with his black-and-white or all-or-nothing thinking. Could DH be too tired to concentrate on some things, but not all things? Might his inability to concentrate be due to a myriad of other factors? *"There must be something wrong with me (if I can't get enough sleep)."* This is catastrophizing and emotional reasoning: just because a person had a feeling does not mean that the thought or feeling is valid. A firmly held belief that sleeplessness negatively affects physical and mental health can set off catastrophizing. (Courtesy of Max Hirshkowitz, Ph.D., Rhoda G. Seplowitz-Hafkin, M.D., and Amir

Sharafkhaneh, M.D., Ph.D.)

Paradoxical Intention. This is a cognitive technique with conflicting evidence regarding its efficacy. In clinical practice, compliance is often a barrier, but it does work for a limited number of patients. The theory is that performance anxiety interferes with sleep onset. Thus, when the patient tries to stay awake for as long as possible rather than trying to fall asleep, performance anxiety will be reduced, and sleep latency will improve.

Hypersomnolence Disorder

We usually treat hypersomnolence disorder with medication. Although there are no medications approved for its treatment, physicians commonly use stimulants, with varying degrees of success. The wake-promoting substance modafinil or traditional psychostimulants (amphetamines and their derivatives) sometimes help manage the sleepiness. In addition to drug therapies, the overall therapeutic approach usually includes lifestyle adjustment, psychological counseling, drug holidays to reduce tolerance (if using stimulants), and careful monitoring of refills, general health, and cardiac status.

Narcolepsy

Currently, we cannot cure narcolepsy; however, the symptoms can be managed with either the wake-promoting substances modafinil or armodafinil, or traditional psychostimulants like amphetamines and their derivatives. The FDA has approved two medications for the treatment of narcolepsy as wake-promoting agents: pitolisant, which is a selective H_3 receptor antagonist/inverse agonist, and solriamfetol, a selective norepinephrine–dopamine reuptake inhibitor. For managing cataplexy, clinicians often administer REM sleep–suppressing drugs (e.g., many antidepressants). This approach capitalizes on the REM sleep-suppressant properties of these drugs. Because cataplexy is presumably an intrusion of REM sleep phenomena into the awake state, the rationale is clear. Many reports indicate that imipramine and protriptyline are quite effective in reducing or eliminating cataplexy. Selective serotonin reuptake inhibitors

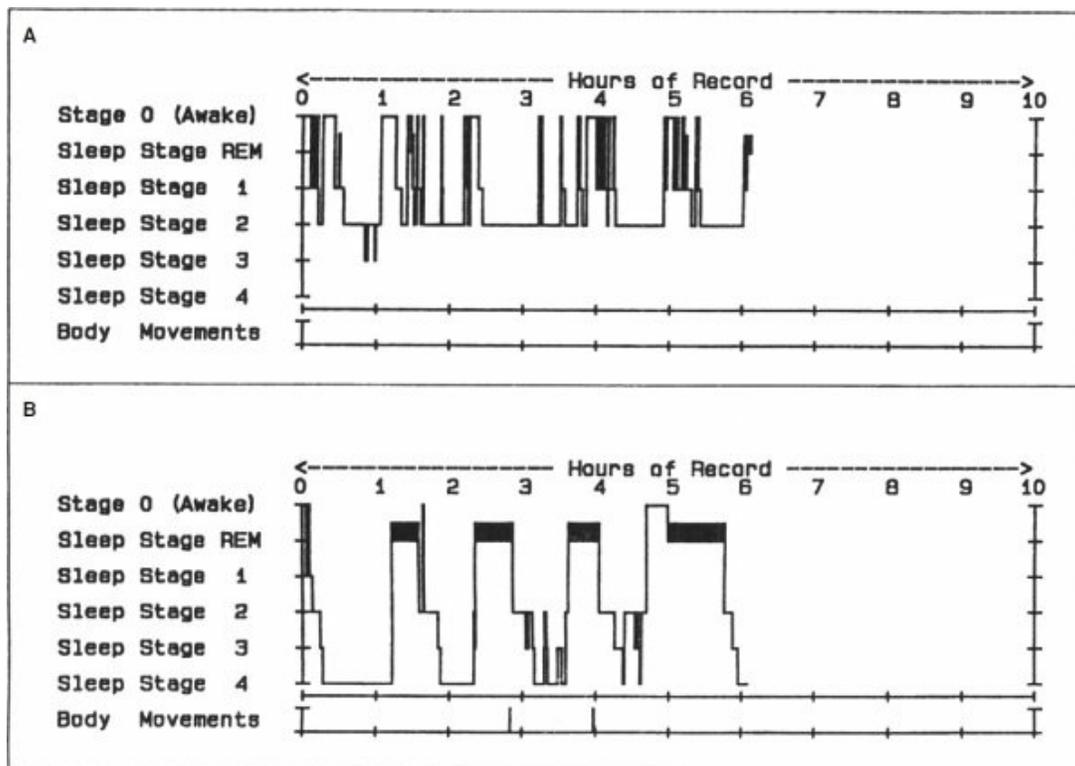
have gained popularity because they are associated with fewer side effects than the tricyclic antidepressants. Sodium oxybate has proven extremely useful for reducing cataplexy, even in cases where clinicians thought that the cataplexy was intractable. Studies also suggest that sodium oxybate helps improve sleep and relieves some of the sleepiness associated with narcolepsy. Although drug therapy is the treatment of choice, the overall therapeutic approach should include scheduled naps, lifestyle adjustment, psychological counseling, drug holidays to reduce tolerance, and careful monitoring of drug refills, general health, and cardiac status.


FIGURE 15-8
Sleep histogram showing CPAP-related sleep improvement. Sleep stage histogram illustrating the immediate, dramatic improvement in sleep architecture produced by treating obstructive sleep apnea with continuous positive airway pressure (CPAP) therapy. **Panel A** illustrates the abnormal sleep pattern on a night when the patient had more than 200 episodes of obstructive sleep apnea. Sleep is disturbed by frequent awakenings while REM and slow-wave (stages 3 and 4) sleep are nearly absent. **Panel B** shows data from the same patient being treated with CPAP on the next night. Normalization of sleep continuity with a massive rebound in REM and slow-wave sleep is evident.

Breathing-Related Sleep Disorders

Obstructive Sleep Apnea-Hypopnea. A number of treatments are available for OSA, including PAP, oral appliances, positional therapy, surgical intervention, and weight loss. Medications have not been useful for treating OSA. Wakefulness promoting agents, such as modafinil, solriamfetol, and pitolisant, may help with the residual sleepiness that may persist despite the use of other OSA treatments such as PAP. However, these medications do not address the pathophysiology of airway occlusion.

POSITIVE AIRWAY PRESSURE. PAP is the preferred treatment for OSA (Fig. 15-8). The PAP apparatus consists of a fan-driven blower, a nasal mask or oronasal interface, and tubing connecting the two. The airflow through the interface (usually a mask or nasal pillows) provides a positive pressure that offsets oropharyngeal collapse produced by inspiratory negative thoracic pressure. In this manner, it acts as a pneumatic splint, thereby maintaining the airway. When appropriately titrating the pressure, even the most severe sleep apnea can be alleviated. Results are often dramatic. PAP devices come in several varieties. The most common are systems that provide a preset continuous positive airway pressure (CPAP). For individuals who find it difficult to exhale against a continuous pressure, bilevel positive airway pressure (BPAP) may provide a solution. BPAP devices have different inspiratory and expiratory pressure settings. More recently, systems that sense the patient's changes in airway resistance and automatically adjust the positive airway pressure have been gaining popularity. Such automatic positive airway pressure (APAP) systems should theoretically be able to adapt to changes in pressure requirements produced by sleep deprivation, medications, weight change, sleep stage, illness, and aging. Finally, there are timed bilevel and servo-ventilation systems, but these fall into the category of noninvasive positive pressure ventilation (NIPPV) systems, which are more appropriate for treating other pulmonary diseases and breathing problems in neuromuscular diseases. The tremendous efficacy and remarkable safety of PAP therapies have made them the standard of care for patients who can tolerate sleeping with the machine. The principal therapeutic challenge is utilization. Patient education and systematic follow-up are crucial. When problems with the interface, the pressure, nasal stuffiness, and other barriers to routine, nightly use arise, we should remedy these quickly to ensure therapeutic adherence. When used properly, the success of PAP therapy has

rendered surgical intervention a secondary option, resorted to mainly after PAP failure, rejection, or nonadherence.

ORAL APPLIANCE. Oral appliances represent another therapeutic option that is gaining popularity. A variety of oral appliances have also been developed to treat snoring and can provide benefit for mild to moderate OSA cases. The general approach is to manipulate the position of the mandible, lift the palate, or retain the tongue. Randomized trials indicate that some oral appliances improve airway patency sufficiently. However, in patients with severe OSA, improvement does not always reach satisfactory levels; therefore, follow-up evaluations are critically important.

POSITIONAL THERAPY. In some patients, sleep-disordered breathing occurs only in the supine position. In such situations, preventing patients from sleeping on their backs may produce beneficial results. Tennis balls sewn onto or placed into pockets on the back of the nightshirt or foam wedges may accomplish this goal. Although such interventions seem to be useful in clinical practice, large-scale systematic clinical trials are needed.

SURGICAL INTERVENTION. Aggressive surgical treatments evolved soon after OSA's pathophysiologic and potentially life-threatening consequences were recognized. The earliest surgical intervention aimed to create a patent airway; thus, in the late 1970s, tracheostomies were performed on individuals with severe apnea. Although no longer the preferred treatment, it remains a standard against which we judge newer, more refined therapies. Second-generation surgical approaches attempt to correct airway obstructions and malformations. Early studies of uvulopalatopharyngoplasty (UPPP) suggested that modification of the soft palate effectively relieved most sleep apnea. Later follow-up results were less impressive. Approximately 30 to 50 percent of patients with sleep apnea benefit from UPPP. These patients are likely those with oropharyngeal obstruction; thus, careful attention to selection criteria presumably improves outcomes. However, if obstruction occurs in the posterior airway space (PAS), maxillomandibular surgery may be appropriate. In retrognathic patients or patients with cephalometrics revealing compromised PAS, moving the jaw forward can achieve impressive normalization of breathing during sleep.

WEIGHT LOSS. Weight loss is known to help many patients. However, because losing weight and keeping it off is difficult and unreliably achieved, the prudent clinician should recommend weight loss but also rely on other therapies.

CSA due to High-Altitude Periodic Breathing. We can treat CSA due to high-altitude periodic breathing with acetazolamide, which lowers serum pH and increases the respiratory drive. Acetazolamide side effects include metabolic acidosis, electrolyte imbalance, anaphylaxis, Stevens–Johnson syndrome, toxic epidermal necrolysis, and agranulocytosis. Common reactions include but are not limited to fatigue, anorexia, taste changes, polyuria, diarrhea, melena, tinnitus, and photosensitivity.

Circadian Rhythm Sleep–Wake Disorders

Light Therapy. Research indicates that exposing an individual to bright lights can reset the circadian pacemaker. This seems especially the case when the light is bright (higher than 10,000 lux) or in the blue spectrum. With the precise timing of bright light exposure, we can reset the biologic clock. Exposure to light modifies the set-point of the biologic clock. Using core body temperature as a physiologic marker, one can use bright lights to produce a phase delay when presented before the temperature nadir. By contrast, light exposure after the temperature nadir evokes phase advance. The closer one presents light to the point of inflection (temperature nadir), the more robust is the response in altering the cycle. Thus, we can use early-morning bright-light therapy to phase advance individuals with delayed sleep phase syndrome.

Similarly, exposure to bright light in the evening can help patients with advanced sleep phase syndrome. The blue part of the light spectrum is the crucial ingredient in phase setting and shifting. Therefore, blue light exposure (or limitation with blue-blocking eyewear) at specific times can provide therapeutic benefit. Clinicians are using light therapy to reset the circadian rhythm of shift workers, astronauts, and individuals experiencing jet lag.

Medication. Researchers posit that melatonin secretion acts as the biologic substrate for the internal circadian oscillator. Under normal circumstances,

melatonin levels begin to rise at dusk and remain elevated until dawn. Bright light suppresses the release of melatonin. Melatonin, in a sense, is the signal of darkness in the brain. As such, we can use it clinically to manage sighted patients with disturbed sleep–wake cycles. Melatonin is available over the counter in the United States. A prescription synthetic melatonin agonist (ramelteon) is also available. Ramelteon is FDA approved for treating patients with sleep-onset insomnia but is used off label for the entire spectrum of circadian rhythm sleep disorders. Outside the United States, a sustained-release prescription form of melatonin is available. Of interest, the only medication approved for shift work sleep disorder is the wake-promoting compound modafinil. Modafinil treats sleepiness occurring during night shift work.

Chronotherapy. Chronotherapy is one technique used to reset the biologic clock. It involves progressively phase delaying a person until synchronizing the circadian oscillator with the desired sleep–wake schedule. Most young and middle-aged adults have a propensity to phase delay the circadian sleep–wake rhythm progressively anyhow. Thus, phase delaying each night by 2 to 3 hours is simpler than phase advancing because it capitalizes on a natural tendency. Halting the phase delay at the appropriate moment and maintaining the desired synchrony can be a challenge. The patient also has to cope with an odd sleep–wake schedule for the better part of a week during therapy (which can interfere with school or work). For these reasons, the development of light therapy and pharmacologic interventions has overshadowed chronotherapy.

Parasomnias and Sleep-Related Movement Disorders

Nightmare Disorder. Treatment using behavioral techniques can be helpful. Desensitization and exposure therapy, image rehearsal therapy, lucid dream therapy, and cognitive therapy can help address nightmare disorder. Additionally, evidence for the use of prazosin, a CNS α-1 receptor antagonist, in the treatment of PTSD-related nightmares is growing. Nitrazepam and triazolam may also be helpful.

Recurrent Isolated Sleep Paralysis. Improved sleep hygiene and

assuring sufficient sleep are first-line therapies. Sometimes, if the individual voluntarily makes very–rapid eye movements or is touched by another person, the episode will usually terminate.

Sleep Enuresis. Treating sleep enuresis involves medication, behavioral interventions, or both. Among medications, desmopressin acetate is the preferred choice. Other medications used to treat sleep enuresis include imipramine and oxybutynin chloride. Behavioral treatments, including bladder training, using conditioning devices (bell and pad), diet modification, and fluid restriction, have reported success when properly administered. Other treatments include psychotherapy, motivational strategies, and hypnotherapy.

Restless Legs Syndrome. Pharmacologically, the dopaminergic agonists pramipexole, rotigotine, and ropinirole are FDA approved and represent the treatment of choice. Other agents used to treat RLS include dopamine precursors (e.g., levodopa), benzodiazepines, opiates (including prolonged-release oxycodone–naloxone), and antiepileptic drugs (e.g., gabapentin, pregabalin). When iron deficiency is present, or when ferritin levels are low, iron supplementation can also be helpful. Nonpharmacologic treatment includes avoiding alcohol or nicotine use close to bedtime, massaging the affected parts of the legs, taking hot baths, applying hot or cold to the affected areas, magnetic or electric stimulation therapy, and moderate exercise.

Periodic Limb Movement Disorder Treatment. Pharmacotherapy for PLMD associated with RLS is the same as for RLS. Clinical trials of pharmacotherapy for other forms of PLMD are lacking. However, benzodiazepines, especially clonazepam, reportedly improve sleep in patients with PLMD.

Sleep-Related Bruxism. The usual treatment involves having the patient wear an oral appliance to protect the teeth during sleep. There are two basic types of appliances: the soft one (mouth guard) is typically used in the short term, whereas the hard acrylic one (bite splint) is used long term and requires regular follow-up. Relaxation, biofeedback, hypnosis, physical therapy, and

stress management can also treat sleep bruxism. A variety of drug therapies have been tried (benzodiazepines, muscle relaxants, dopaminergic agonists, and propranolol); however, reliable outcome data are not available. Botulinum toxin can also improve the frequency of bruxism episodes.

Benign Sleep Myoclonus of Infancy. This benign condition typically lasts a few days to several months and does not need to be treated.

Propriospinal Myoclonus at Sleep Onset. Treatment with clonazepam or anticonvulsants may be useful.

Human Sexuality and Sexual Dysfunctions

Sexuality is a broad topic, and no brief synopsis can do it justice. For the psychiatrist, it loosely divides into the subjects of normal sexuality, sexual dysfunction, paraphilias, and gender dysphoria. As with other chapters, we are focusing on the disorders that might bring a patient to a psychiatrist. There are two broad categories of disorders that we loosely group under sexual disorders: sexual dysfunction and paraphilias. By sexual dysfunctions, we are referring to disorders of normal sexual functioning. The paraphilias are unusual expressions of sexuality that are considered aberrant or even illegal. As these represent fundamentally different problems that require very different approaches, we separate these into two sections. We then discuss normal sexuality as part of our consideration of the pathology and etiology of these disorders. We will discuss gender dysphoria in the next section.

For a fuller discussion, we would refer the reader to Virginia Sadock's excellent review of the subject in the *Comprehensive Textbook.*

SEXUAL DYSFUNCTIONS

The essential features of sexual dysfunctions are an inability to respond to sexual stimulation, or the experience of pain during the sexual act. Dysfunction can be defined by a disturbance in the subjective sense of pleasure or desire usually associated with sex, or by the objective performance. According to ICD-10, sexual dysfunction refers to a person's inability "to participate in a sexual relationship as he or she would wish."

In DSM-5, the sexual dysfunctions include male hypoactive sexual desire disorder, female sexual interest/arousal disorder, erectile disorder, female

orgasmic disorder, delayed ejaculation, premature (early) ejaculation, genito-pelvic pain/penetration disorder, substance/medication-induced sexual dysfunction, other specified sexual dysfunction, and unspecified sexual dysfunction. We diagnose sexual dysfunctions only when they are a significant part of the clinical picture. If more than one dysfunction exists, we should diagnose them all. Sexual dysfunctions can be lifelong or acquired, generalized or situational, and result from psychological factors, physiologic factors, combined factors, and numerous stressors, including prohibitive cultural mores, health and partner issues, and relationship conflicts. If the dysfunction is attributable entirely to a general medical condition, substance use, or adverse effects of medication, then sexual dysfunction due to a general medical condition or substance-induced sexual dysfunction is diagnosed. DSM-5 indicates the severity of the dysfunction by whether the patient's distress is mild, moderate, or severe.

Sexual dysfunctions are frequently associated with other mental disorders, such as depressive disorders, anxiety disorders, personality disorders, and schizophrenia. In many instances, sexual dysfunction is comorbid with another psychiatric disorder. If the dysfunction is mostly attributable to an underlying psychiatric disorder, we should only diagnose the underlying disorder. Sexual dysfunctions are usually self-perpetuating, with the patients increasingly subjected to ongoing performance anxiety and a concomitant inability to experience pleasure. In relationships, the sexually functional partner often reacts with distress or anger due to feelings of deprivation or a sense that he or she is an insufficiently attractive or adequate sexual partner. In such cases, the clinician must consider whether the sexual problem preceded or arose from relationship difficulties and weigh whether a diagnosis of sexual dysfunction relevant to relationship issues is appropriate.

A sex history provides essential information about patients, regardless of the presence of a sexual disorder or whether that is the patient's chief complaint. The information can be obtained gradually through open-ended questions. The outline in Table 16-1 provides a guide to the topics to be covered.

Desire, Interest, and Arousal Disorders

Male Hypoactive Sexual Desire Disorder. Male hypoactive sexual

desire disorder is a deficiency or absence of sexual fantasies and desire for sexual activity for a minimum duration of approximately 6 months (Table 16-2). Men for whom this is a lifelong condition have never experienced many spontaneous erotic/sexual thoughts. Minimal spontaneous sexual thinking or minimal desire for sex ahead of sexual experiences is not a diagnosable disorder in women, primarily if the sexual encounter then triggers the desire. The reported prevalence of low desire is highest at the younger and older ends of the age spectrum, with only 2 percent of men ages 16 to 44 affected by this disorder. A reported 6 percent of men ages 18 to 24, and 40 percent of men ages 66 to 74, have problems with sexual desire. Some men may confuse decreased desire with decreased activity. Their erotic thoughts and fantasies are undiminished, but they no longer act on them due to health issues, unavailability of a partner, or another sexual dysfunction such as erectile disorder.

A variety of causative factors are associated with low sexual desire. Patients with desire problems often use inhibition of desire defensively, to protect against unconscious fears about sex.

Abstinence from sex for a prolonged period sometimes results in suppression of sexual impulses. Loss of desire may also be an expression of hostility to a partner or the sign of a deteriorating relationship. The presence of desire depends on several factors: biologic drive, adequate self-esteem, the ability to accept oneself as a sexual person, the availability of an appropriate partner, and a good relationship in nonsexual areas with a partner. Damage to, or absence of, any of these factors can diminish desire.

In making the diagnosis, clinicians must evaluate a patient's age, general health, any medication regimen, and life stresses. The clinician must attempt to establish a baseline of sexual interest before the disorder began. The need for sexual contact and satisfaction varies among persons. We should not make a diagnosis unless the lack of desire is a source of distress to a patient.

**Table 16-1
Taking a Sex History**

I. Identifying data
  A. Age
  B. Sex

C. Occupation

D. Relationship status—single, married, number of times previously married, separated, divorced, cohabiting, serious involvement, casual dating (difficulty forming or keeping relationships should be assessed throughout the interview)

E. Sexual orientation—heterosexual, homosexual, or bisexual (this may also be ascertained later in the interview)

II. Current functioning

A. Unsatisfactory to highly satisfactory

B. If unsatisfactory, why?

C. Feeling about partner satisfaction

D. Dysfunctions?—e.g., lack of desire, erectile disorder, inhibited female interest/arousal, anorgasmia, premature ejaculation, retarded ejaculation, pain associated with intercourse (dysfunction discussed below)

   1. Onset—lifelong or acquired
      a. If acquired, when?
      b. Did onset coincide with drug use (medications or illegal recreational drugs), life stresses (e.g., loss of job, birth of child), interpersonal difficulties

   2. Generalized—occurs in most situations or with most partners

   3. Situational
      a. Only with current partner
      b. In any committed relationship
      c. Only with masturbation
      d. In socially proscribed circumstance (e.g., affair)
      e. In definable circumstance (e.g., very late at night, in parental home, when partner initiated sex play)

E. Frequency—partnered sex (coital and noncoital sex play)

F. Desire/libido—how often are sexual feelings, thoughts, fantasies, dreams, experienced? (per day, week, etc.)

G. Description of typical sexual interaction
   1. Manner of initiation or invitation (e.g., verbal or physical? Does same person always initiate?)

2. Presence, type, and extent of foreplay (e.g., kissing, caressing, manual or oral genital stimulation)
3. Coitus? positions used?
4. Verbalization during sex? if so, what kind?
5. Afterplay? (whether sex act is completed or disrupted by dysfunction); typical activities (e.g., holding, talking, return to daily activities, sleeping)
6. Feeling after sex: relaxed, tense, angry, loving

H. Sexual compulsivity?—intrusion of sexual thoughts or participation in sexual activities to a degree that interferes with relationships or work, requires deception and may endanger the patient

III. Past sexual history
A. Childhood sexuality
1. Parental attitudes about sex—degree of openness or reserve (assess unusual prudery or seductiveness)
2. Parents' attitudes about nudity and modesty
3. Learning about sex
   a. From parents? (initiated by child's questions or parent volunteering information? which parent? what was child's age?) subjects covered (e.g., pregnancy, birth, intercourse, menstruation, nocturnal emission, masturbation)
   b. From books, magazines, or friends at school or through religious group?
   c. Significant misinformation
   d. Feeling about information
4. Viewing or hearing primal scene—reaction?
5. Viewing sex play or intercourse of person other than parent
6. Viewing sex between pets or other animals

B. Childhood sex activities
1. Genital self-stimulation before adolescence; age? reaction if apprehended?
2. Awareness of self as boy or girl; bathroom sensual activities? (regarding urine, feces, odor, enemas)

3. Sexual play or exploration with another child (playing doctor)—type of activity (e.g., looking, manual touching, genital touching); reactions or consequences if apprehended (by whom?)

IV. Adolescence
   A. Age of onset of puberty—development of secondary sex characteristics, age of menarche for girl, wet dreams or first ejaculation for boy (preparation for and reaction to)
   B. Sense of self as feminine or masculine—body image, acceptance by peers (opposite sex and same sex), sense of sexual desirability, onset of coital fantasies
   C. Sex activities
      1. Masturbation—age begun; ever punished or prohibited? method used, accompanying fantasies, frequency (questions about masturbation and fantasies are among the most sensitive for patients to answer)
      2. Homosexual activities—ongoing or rare and experimental episodes, approached by others? If homosexual, has there been any heterosexual experimentation?
      3. Dating—casual or steady, description of first crush, infatuation, or first love
      4. Experiences of kissing, necking, petting ("making out" or "fooling around"), age begun, frequency, number of partners, circumstances, type(s) of activity
      5. Orgasm—when first experienced? (may not be experienced during adolescence), with masturbation, during sleep, or with partner? with intercourse or other sex play? frequency?
      6. First coitus—age, circumstances, partner, reactions (may not be experienced during adolescence); contraception and/or safe sex precautions used

V. Adult sexual activities (may be experienced by some adolescents)
   A. Premarital sex
      1. Types of sex play experiences—frequency of sexual interactions, types and number of partners

2. Contraception and/or safe sex precautions used
3. First coitus (if not experienced in adolescence) age, circumstances, partner
4. Cohabitation—age begun, duration, description of partner, sexual fidelity, types of sexual activity, frequency, satisfaction, number of cohabiting relationships, reasons for breakup(s)
5. Engagement—age, activity during engagement period with fiancé(e), with others; length of engagement

B. Marriage (if multiple marriages have occurred, explore sexual activity, reasons for marriage, and reasons for divorce in each marriage)
1. Types and frequency of sexual interaction—describe typical sexual interaction (see above), satisfaction with sex life? view of partner's feeling
2. First sexual experience with spouse—when? what were the circumstances? was it satisfying? disappointing?
3. Honeymoon—setting, duration, pleasant or unpleasant, sexually active, frequency? problems? compatibility?
4. Effect of pregnancies and children on marital sex
5. Extramarital sex—number of incidents, partner; emotional attachment to extramarital partners? feelings about extramarital sex
6. Postmarital masturbation—frequency? effect on marital sex?
7. Extramarital sex by partner—effect on interviewee
8. Ménage à trois or multiple sex (swinging)
9. Areas of conflict in marriage (e.g., parenting, finances, division of responsibilities, priorities)

VI. Sex after widowhood, separation, divorce—celibacy, orgasms in sleep, masturbation, noncoital sex play, intercourse (number of and relationship to partners), other

VII. Special issues
A. History of rape, incest, sexual or physical abuse
B. Spousal abuse (current)

C. Chronic illness (physical or psychiatric)

D. History or presence of sexually transmitted diseases

E. Fertility problems

F. Abortions, miscarriages, or unwanted or illegitimate pregnancies

G. Gender identity conflict—(e.g., transsexualism, wearing clothes of opposite sex)

H. Paraphilias—(e.g., fetishes, voyeurism, sadomasochism)

Female Sexual Interest/Arousal Disorder. The combination of interest (or desire) and arousal into one dysfunction category reflects the recognition that women do not necessarily move stepwise from desire to arousal, but often experience desire synchronously with, or even following, beginning feelings of arousal. This is particularly true for women in long-term relationships. As a corollary, women experiencing sexual dysfunction may experience either inability to feel interest or arousal, and they may also have difficulty achieving orgasm or experience pain. Some may experience dysfunction across the entire range of sexual response. Complaints in this dysfunction category present variously as a decrease or paucity of erotic feelings, thoughts, or fantasies; a decreased impulse to initiate sex; a decreased or absent receptivity to partner overtures; or an inability to respond to partner stimulation (Table 16-3).

A complicating factor in this diagnosis is that a subjective sense of arousal is often poorly correlated with genital lubrication in both normal and dysfunctional women. Therefore, complaints of lack of pleasure are sufficient for this diagnosis even when vaginal lubrication and congestion are present. A woman complaining of lack of arousal may lubricate vaginally, but may not experience a subjective sense of excitement. Alterations in testosterone, estrogen, prolactin, and thyroxin levels occur in female sexual arousal

disorder. Also, medications with antihistaminic or anticholinergic properties cause a decrease in vaginal lubrication.

We should evaluate factors such as life stresses, aging, menopause, adequate sexual stimulation, and general health before making this diagnosis. Relationship problems are particularly relevant to acquired interest/arousal disorder. In one study of couples with markedly decreased sexual interaction, the most prevalent etiology was marital discord.

Male Erectile Disorder. Male erectile disorder was historically called *impotence.* The term was dropped for a more medical designation, but also because it was considered derogatory and had negative connotations for the man with the problem. However, it describes with accuracy the feelings of powerlessness, helplessness, and resultant low self-esteem men with this dysfunction frequently suffer (Table 16-4). A man with a lifelong male erectile disorder has never been able to obtain an erection sufficient for insertion. In acquired male erectile disorder, a man has successfully achieved penetration at some time in his sexual life but is later unable to do so. In situational male erectile disorder, a man can have coitus in certain circumstances but not in others; for example, he may function effectively with a sex worker but be unable to have an erection when with his partner.

Acquired male erectile disorder occurs in 10 to 20 percent of all men. Erectile disorder is the chief complaint of more than 50 percent of all men treated for sexual disorders. Lifelong male erectile disorder is rare; it occurs in about 1 percent of men younger than age 35. The incidence of erectile disorder increases with age. It has been reported variously as 2 to 8 percent of the young adult population, and much more common in older men. Male erectile disorder, however, is not universal in aging men; having an available sex partner is related to continuing potency, as is a history of consistent sexual activity and the absence of vascular, neurologic, or endocrine disease. Twenty percent of men fear erectile dysfunction before their first coitus; the reported incidence of actual erectile dysfunction during the first coitus is 8 percent.

Male erectile disorder can be organic or psychological or a combination of both, but in young and middle-aged men, the cause is usually psychological. A good history is of primary importance in determining the cause of the dysfunction. If a man reports having spontaneous erections at times when he

does not plan to have intercourse, having morning erections, or having good erections with masturbation or with partners other than his usual one, the physiologic causes of his erectile disorder can be considered negligible, and he can avoid costly diagnostic procedures. Male erectile disorder caused by a general medical condition or a pharmacologic substance is discussed later in this section.

		    diagnosis as including male
		    erectile disorder as well as
		    female sexual arousal disorder

A man may be unable to express a sexual impulse because of fear, anxiety, anger, or moral prohibition. In an ongoing relationship, the disorder may reflect difficulties between the partners, mainly when a man cannot communicate his needs or his anger directly and constructively. Also, episodes of erectile disorder are reinforcing, with the man becoming increasingly anxious before each sexual encounter.

Mr. Y came for therapy after his wife complained about their lack of sexual interaction. The patient avoided sex because of his frequent erectile dysfunction and the painful feelings of inadequacy he suffered after his "failures." He presented as an articulate, gentle, and self-blaming man.

He was faithful to his wife but masturbated frequently. His fantasies involved explicit sadistic components, including hanging and biting women. The contrast between his angry, aggressive fantasies and his loving, considerate behavior toward his wife symbolized his conflicts about his sexuality, his masculinity, and his mixed feelings about women. The physician diagnosed him with erectile disorder, situational type.

Orgasm Disorders

Female Orgasmic Disorder. Female orgasmic disorder, sometimes called *inhibited female orgasm* or *anorgasmia*, is defined as the recurrent or persistent inhibition of female orgasm, as manifested by the recurrent delay in, or absence of, orgasm after a normal sexual excitement phase that a clinician judges to be adequate in focus, intensity, and duration—in short, a woman's inability to achieve orgasm by masturbation or coitus (Table 16-5). Women who can achieve orgasm by one of these methods are not necessarily categorized as anorgasmic, although there may be some sexual inhibition. Some anorgasmic women are not distressed by the lack of climax and derive pleasure from sexual activity. However, the woman may still present for treatment as her partner is distressed by her apparent disinterest.

Research on the physiology of the female sexual response has shown that orgasms caused by clitoral stimulation and those caused by vaginal stimulation are physiologically identical. Many women achieve orgasm during coitus by a combination of manual clitoral stimulation and penile vaginal stimulation.

A woman with a lifelong female orgasmic disorder has never experienced orgasm by any kind of stimulation. A woman with an acquired orgasmic disorder has previously experienced at least one orgasm, regardless of the circumstances or means of stimulation, whether by masturbation or while

dreaming during sleep. Studies have shown that women achieve orgasm more consistently with masturbation than with partnered sex. Lifelong female orgasmic disorder is more common among unmarried women than married women. Increased orgasmic potential in women older than 35 years of age may relate to less psychologic inhibition, greater sexual experience, or both.

Acquired female orgasmic disorder is a common complaint in clinical populations. One clinical treatment facility reported having about four times as many nonorgasmic women in its practice as female patients with all other sexual disorders. In another study, 46 percent of women complained of difficulty reaching orgasm. Inhibition of arousal and orgasmic problems often occur together. The overall prevalence of female orgasmic disorder from all causes is estimated to be 30 percent. Orgasmic dysfunction in some females may have a genetic basis and cannot be attributed solely to psychologic differences. That study demonstrated an estimated heritability for difficulty reaching orgasm with intercourse of 34 percent and an estimated heritability in women who could not climax with masturbation of 45 percent.

Table 16-5
Female Orgasmic Disorder

	DSM-5	ICD-10
Name	Female Orgasmic Disorder	Orgasmic dysfunction

	(including prescribed meds) Another medical condition Another psychiatric condition	
Psychosocial Impact	Marked distress	
Symptom Specifiers	Generalized vs. Situational	
Severity Specifiers	**Mild:** causes mild distress **Moderate:** causes moderate distress **Severe:** causes severe distress	
Course Specifiers	Lifelong vs. Acquired Never experienced an orgasm under any conditions	
Comments		Note: ICD 10 classifies orgasmic dysfunction as occurring in men and women, including delayed ejaculation in this category as per Table 16-6

Numerous psychological factors are associated with female orgasmic disorder. They include fears of impregnation, rejection by a sex partner, and damage to the vagina; hostility toward men; poor body image; and feelings of guilt about sexual impulses. Some women equate orgasm with loss of control or with aggressive, destructive, or violent impulses; they may express their

fear of these impulses through inhibition of arousal or orgasm. Cultural expectations and social restrictions on women are also relevant. Despite the sexual revolution of the 1960s, many women in the United States still grow to believe that sexual pleasure is not a natural entitlement for so-called decent women. Nonorgasmic women may be otherwise symptom-free or may experience frustration in a variety of ways; they may have such pelvic complaints as lower abdominal pain, itching, and vaginal discharge, as well as increased tension, irritability, and fatigue.

Delayed Ejaculation. In male delayed ejaculation, sometimes called *retarded ejaculation,* a man achieves ejaculation during coitus with great difficulty, if at all (Table 16-6). The problem is rarely present with masturbation but appears as a problem during partnered sex. A man with lifelong delayed ejaculation has never been able to ejaculate during partnered sexual activity. The problem is usually most pronounced during coital activity. We would consider the disorder to be acquired if it develops after previously normal functioning. Some researchers think that orgasm and ejaculation should be differentiated, especially in the case of men who ejaculate but complain of a decreased or absent subjective sense of pleasure during the orgasmic experience (orgasmic anhedonia).

The incidence of male orgasmic disorder is much lower than the incidence of premature ejaculation or erectile disorder. The prevalence is about 5 percent. However, there may be an increase in this disorder presenting to sex therapy programs. An increase in antidepressant use may be one explanation for this. Another is the high use of Internet pornography. These sites offer a level of stimulation involving such a variety of people and acts that they may inure the man to the stimulation of more typical partnered activity. Some studies of adolescent males who use these sites frequently, before live sexual interaction, have reported that these teens do not develop neuronal synapses that will enable them to respond to usual partnered interactions with sufficient pleasure to allow them to achieve climax.

Lifelong delayed ejaculation indicates severe psychopathology. A man may come from a rigid, puritanical background; he may perceive sex as sinful and the genitals as dirty, and he may have conscious or unconscious incest wishes and guilt. He usually has difficulty with closeness in areas beyond those of sexual relations. In a few cases, an attention-deficit/hyperactivity

disorder may aggravate the condition. A man's distractibility prevents sufficient arousal for climax to occur.

In an ongoing relationship, acquired male delayed ejaculation disorder frequently reflects interpersonal difficulties. The disorder may be a man's way of coping with real or fantasized changes in a relationship, such as plans for pregnancy about which the man is ambivalent, the loss of sexual attraction to the partner, or demands by the partner for greater commitment as expressed by sexual performance. In some men, the inability to ejaculate reflects unexpressed hostility toward a woman. The problem is more common among men with obsessive-compulsive disorder (OCD) than among others.

Course Specifiers	Lifelong vs. Acquired	
Comments		Note: ICD 10 classifies orgasmic dysfunction as occurring in men and women, including delayed ejaculation in this category as per Table 16-5

A couple presented with the man as the identified patient; he was unable to ejaculate with intercourse. He had always had difficulty reaching climax, except in rare circumstances. He ejaculated once when he was with two women at the same time and once when he was experimenting with cocaine. He currently was not using any substances except for

moderate use of alcohol. This patient was committed to his marriage, although he had extramarital sexual experiences. He did not ejaculate with coitus in those situations either, although he could climax with oral sex. He stated he was more interested in "the conquest" than in the sex itself. He could climax with masturbation, although he rarely masturbated himself, but went to massage parlors. He had issues with anger at women and considered his wife to be excessively critical.

He had difficulty doing any of the exercises that required him to pleasure his wife. His difficulty giving also made it hard for him to enjoy mutual pleasuring. It was easier for him to be the recipient of stimulation. Because of this patient's problems with impulsiveness, narcissism, and dependency, it was necessary to combine introspective psychotherapy with a regimen of behavioral exercises.

The psychiatrist diagnosed the patient with delayed ejaculation, lifelong type.

Premature (Early) Ejaculation. In premature ejaculation, men persistently or recurrently achieve orgasm and ejaculation before they wish to. The diagnosis occurs when a man regularly ejaculates before or within approximately 1 minute after penetration. DSM-5 refers only to "vaginal penetration" in its diagnostic criteria, even though the disorder can occur in gay men or those who do not engage in vaginal penetration for other reasons. DSM-5 defines the disorder as mild if ejaculation occurs within approximately 30 seconds to 1 minute of vaginal penetration, moderate if ejaculation occurs within approximately 15 to 30 seconds of vaginal penetration, and severe when ejaculation occurs at the start of sexual activity or within approximately 15 seconds of vaginal penetration. A difficulty with these specifiers involves time distortions, which patients make in both overestimating and underestimating time from penetration to climax. Clinicians need to consider factors that affect the duration of the excitement phase of the sexual response, such as age, the novelty of the sex partner, and the frequency of coitus (Table 16-7). As with the other sexual dysfunctions, we would not diagnose premature ejaculation when it is caused exclusively by organic factors or when it is symptomatic of another clinical psychiatric syndrome.

Premature ejaculation appears to be more common among college-educated men than among men with less education. The complaint is likely related to their concern for partner satisfaction, although data is limited, and we do not know for sure. Premature ejaculation is the chief complaint of about 35 to 40 percent of men treated for sexual disorders. In DSM-5, the writers state that the disorder, with its newly defined time parameter, would now be an accurate diagnosis for only 1 to 3 percent of men. Some researchers divide men who experience premature ejaculation into two groups: those who are physiologically predisposed to climax quickly because of shorter nerve latency time and those with a psychogenic or behaviorally conditioned cause. Difficulty in ejaculatory control can be associated with anxiety regarding the sex act, with unconscious fears about the vagina, or with negative cultural conditioning. Men whose early sexual contacts occurred mainly with sex workers who demanded that the sex act proceed quickly or whose sexual contacts took place in situations in which discovery would be embarrassing (e.g., in a shared dormitory room or the parental home) may be conditioned to orgasm rapidly. With young, inexperienced men, who have the problem, it may resolve in time. In ongoing relationships, the partner has a significant influence on a premature ejaculator, and a stressful marriage exacerbates the disorder. The developmental background and the psychodynamics found in premature ejaculation and erectile disorder are similar.

Table 16-7
Premature (Early) Ejaculation

	DSM-5	ICD-10
Name	Premature (Early) Ejaculation	Premature ejaculation
Duration	≥6 mo	
Symptoms	Ejaculation occurs Within 1 min of penetration Before it was	Difficulty controlling ejaculation

	intended	
# Symptoms Needed	Above occurs in most sexual encounters	
Exclusions (not result of):	Relationship problem Substance use (including prescribed meds) Another medical condition Another psychiatric condition	
Psychosocial Impact	Marked distress	Both partners do not sufficiently enjoy the sexual encounter
Symptom Specifiers	Generalized vs. Situational	
Severity Specifiers	Defined by time from penetration until ejaculation: **Mild:** 30 s–1 min **Moderate:** 15–30 s **Severe:** <15 s	
Course Specifiers	Lifelong vs. Acquired	

The focus of this diagnosis is on males, and data on premature female orgasm are lacking. There are some case reports of, for example, multiple spontaneous orgasms without sexual stimulation. In some cases, an epileptogenic focus may be the cause. There are also some rare case reports of spontaneous orgasms in women taking serotonergic antidepressants.

Orgasmic Anhedonia. Orgasmic anhedonia is a condition in which a

person has no physical sensation of orgasm, even though the physiologic component (e.g., ejaculation) remains intact. Organic causes, such as sacral and cephalic lesions that interfere with afferent pathways from the genitalia to the cortex, must be ruled out. Psychiatric causes usually relate to extreme guilt about experiencing sexual pleasure. These feelings produce a dissociative response that isolates the affective component of the orgasmic experience from consciousness. In DSM-5 this would be diagnosed as an "other specified sexual dysfunction."

Sexual Pain Disorders

Genito-Pelvic Pain/Penetration Disorder. In DSM-5, this disorder refers to one or more of the following complaints, of which any two or more may occur together: difficulty having intercourse, genito-pelvic pain, fear of pain or penetration, and tension of the pelvic floor muscles (Table 16-8). Previously, we diagnosed these pain disorders as *dyspareunia* or *vaginismus*. These former diagnoses could coexist, or one could lead to the other and could understandably lead to fear of pain with sex. Thus, it is reasonable to gather these diagnoses into one diagnostic category. For this clinical discussion, however, the distinct categories of dyspareunia and vaginismus remain clinically useful.

DYSPAREUNIA. Dyspareunia is recurrent or persistent genital pain occurring before, during, or after intercourse. Dyspareunia is related to and often coincides with vaginismus. Repeated episodes of vaginismus can lead to dyspareunia and vice versa; in either case, we should rule out somatic causes, or lack of lubrication. Perhaps 5 percent of women in North America report recurrent pain during intercourse.

In most cases, dynamic factors are considered causative. Chronic pelvic pain is a common complaint in women with a history of rape or childhood sexual abuse. Painful coitus can result from tension and anxiety about the sex act that causes women to contract their pelvic floor muscles involuntarily. The pain is real and makes intercourse unpleasant or unbearable. The anticipation of further pain may cause women to avoid coitus altogether. If a partner proceeds with intercourse regardless of a woman's state of readiness, this aggravates the condition. There is an increase in reported dyspareunia

postmenopausally due to hormonally induced physiologic changes in the vagina; however, specific complaints of difficulty having intercourse occur more often in premenopausal women. There is some increase in dyspareunia in the immediate postpartum population, but it is usually temporary. Dyspareunia may present as any of the four complaints listed under genito-pelvic pain/penetration disorder, and we would diagnose this as a genito-pelvic pain/penetration disorder.

VAGINISMUS. Vaginismus is a constriction of the outer third of the vagina due to involuntary pelvic floor muscle tightening or spasm. It then interferes with penile insertion and intercourse. This response may occur during a gynecologic examination when involuntary vaginal constriction prevents the introduction of the speculum into the vagina. We would not make the diagnosis when the dysfunction is caused exclusively by organic factors or when it is symptomatic of another mental disorder.

Vaginismus may be complete; that is, no penetration of the vagina is possible, whether by the penis, fingers, a speculum during a gynecologic examination, or even if the woman tries to use the smallest size tampon. Many women who discover this when they become sexually active have avoided the use of tampons previously. In a less severe form of vaginismus, pelvic floor muscle tightening due to pain or fear of pain makes penetration difficult, but not impossible. Penetration may be achieved with the smallest size speculum or little fingers. In mild cases, the muscles relax after the initial difficulty with penetration, and the woman can continue with sexual play, sometimes even with coitus.

Miss B was a 27-year-old single woman who presented for therapy because of an inability to have intercourse. She described episodes with a recent boyfriend in which he had tried vaginal penetration but had been unable to enter. The boyfriend did not have erectile dysfunction. Miss B experienced desire and was able to achieve orgasm through manual or oral stimulation. For almost a year, she and her boyfriend had sex play without intercourse. However, he complained increasingly about his frustration at the lack of coitus, which he had enjoyed in previous relationships. Miss B had a conscious fear of penetration and dreaded

going to the gynecologist, although she was able to use tampons when she menstruated. Her therapist diagnosed her with genito-pelvic pain/penetration disorder, lifelong type.

Table 16-8
Genito-Pelvic Pain/Penetration Disorder

	DSM-5	ICD-10
Name	**Genito-Pelvic Pain/Penetration Disorder**	**Nonorganic vaginismus Nonorganic dyspareunia**
Duration	≥6 mo	
Symptoms	During vaginal penetration, the woman experiences Difficulties with penetration Pain Associated symptoms during or in anticipation of penetration: Fear or anxiety Tension or tightening of pelvic muscles	*Vaginismus*: spasm of pelvic floor muscles around the vagina, causing pain and difficulties with penetration Dyspareunia: pain or discomfort related to penile penetration or intercourse
# Symptoms Needed	One or more of the above	
Exclusions (not result of):	Relationship problem Substance use	Another medical condition

	(including prescribed meds)
	Another medical condition
	Another psychiatric condition

Symptom Specifiers	
Severity Specifiers	**Mild:** causes mild distress
	Moderate: causes moderate distress
	Severe: causes severe distress
Course Specifiers	Lifelong vs. Acquired

Vaginismus is less prevalent than female orgasmic disorder. It most often afflicts highly educated women and those in high socioeconomic groups. Women with vaginismus may consciously wish to have coitus, but unconsciously wish to keep a penis from entering their bodies. Sexual trauma, such as rape, may cause vaginismus. The anticipation of pain at the first coital experience may cause vaginismus. Clinicians have noted that a strict religious upbringing in which the patient associates sex with sin is frequent in these patients. Other women have problems in dyadic relationships; if women feel emotionally abused by their partners, they may protest in this nonverbal fashion. Some women who have experienced significant pain in childhood due to surgical or dental interventions become guarded about any breach of body integrity and develop vaginismus. Vaginismus may present as any of the four complaints under genito-pelvic

pain/penetration disorder, and we should diagnose this as genito-pelvic pain/penetration disorder.

Postcoital Headache. Postcoital headache, characterized by headache immediately after coitus, may last for several hours. It is usually described as throbbing and localized to the occipital or frontal area. The cause is unknown. There may be vascular, muscle contraction (tension), or psychogenic causes. Coitus may precipitate migraine or cluster headaches in predisposed persons. In DSM-5 this disorder would not be included among the above pain disorders as the pain is not directly associated with the sexual act. When it is a source of distress or dysfunction, we list it as an "other specified sexual dysfunction."

Sexual Dysfunction due to a General Medical Condition

Male Erectile Disorder due to a General Medical Condition. The incidence of psychological male erectile disorder has been the focus of many studies. Statistics indicate that 20 to 50 percent of men with erectile disorder have an organic basis for the disorder. A physiologic etiology is more likely in men older than 50 and the most likely cause in men older than age 60. Table 16-9 lists the medical causes of male erectile disorder. Side effects of medication can impair male sexual functioning in a variety of ways (Table 16-10). Castration (removal of the testes) does not always lead to sexual dysfunction because erection may still occur. A reflex arc, fired when stimulating the inner thigh, passes through the sacral cord erectile center to account for the phenomenon.

Several procedures, benign and invasive, are used to help differentiate the causes of erectile disorder. The procedures include monitoring nocturnal penile tumescence (erections that occur during sleep), generally associated with rapid eye movement; monitoring tumescence with a strain gauge; measuring blood pressure in the penis with a penile plethysmograph or an ultrasound (Doppler) flowmeter, both of which assess blood flow in the internal pudendal artery; and measuring pudendal nerve latency time. Other diagnostic tests that delineate physiologic bases for impotence include glucose tolerance tests, plasma hormone assays, liver and thyroid function tests, prolactin and follicle-stimulating hormone (FSH) determinations, and

cystometric examinations. Invasive diagnostic studies include penile arteriography, infusion cavernosonography, and radioactive xenon penography. Invasive procedures require expert interpretation and are used only for patients who are candidates for vascular reconstructive procedures.

Dyspareunia due to a General Medical Condition. An estimated 30 percent of all surgical procedures on the female genital area result in temporary dyspareunia. Also, 30 to 40 percent of women with the complaint seen in sex therapy clinics have pelvic pathology. Organic abnormalities leading to dyspareunia and vaginismus include irritated or infected hymenal remnants, episiotomy scars, Bartholin gland infection, various forms of vaginitis and cervicitis, endometriosis, and adenomyosis. Women with myomata, endometriosis, and adenomyosis may report postcoital pain owing to the uterine contractions during orgasm. Postmenopausal women may have dyspareunia resulting from thinning of the vaginal mucosa and reduced lubrication.

Table 16-9
Diseases and Other Medical Conditions Implicated in Male Erectile Disorder

Infectious and parasitic diseases	Neurologic disorders
	Multiple sclerosis
	Transverse myelitis
Elephantiasis	Parkinson disease
Mumps	Temporal lobe epilepsy

Herbicides
Surgical procedures[a]
Perineal prostatectomy
Abdominal–perineal colon resection
Sympathectomy (frequently interferes with ejaculation)
Aortoiliac surgery
Radical cystectomy
Retroperitoneal lymphadenectomy
Miscellaneous
Radiation therapy
Pelvic fracture
Any severe systemic disease or debilitating condition

Adrenal neoplasia
Myxedema
Hyperthyroidism

[a]In the United States an estimated 2 million men are impotent because they have diabetes mellitus; an additional 300,000 are impotent because of other endocrine diseases; 1.5 million are impotent as a result of vascular disease; 180,000 because of multiple sclerosis; 400,000 because of traumas and fractures leading to pelvic fractures or spinal cord injuries; and another 650,000 are impotent as a result of radical surgery, including prostatectomies, colostomies, and cystectomies.

Two conditions not readily apparent on physical examination that produce dyspareunia are vulvar vestibulitis and interstitial cystitis. The former may present with chronic vulvar pain, and the latter produces pain most intensely following orgasm. Dyspareunia can also occur in men, but it is uncommon and is usually associated with an organic condition, such as Peyronie disease, which consists of sclerotic plaques on the penis that cause penile curvature.

Male Hypoactive Sexual Desire Disorder and Female Interest/Arousal Disorder due to a General Medical Condition. Sexual desire commonly decreases after major illness or surgery, particularly when the body image is affected after such procedures as mastectomy, ileostomy, hysterectomy, and prostatectomy. Illnesses that deplete a person's energy, chronic conditions that require physical and psychological adaptation, and serious illnesses that can cause a person to become depressed can all markedly lessen sexual desire.

In some cases, biochemical correlates are associated with hypoactive sexual desire disorder (Table 16-11). A recent study found markedly lower levels of serum testosterone in men complaining of low desire than in normal controls in a sleep-laboratory situation. Drugs that depress the central nervous system (CNS) or decrease testosterone production can decrease desire.

Other Male Sexual Dysfunction due to a General Medical Condition. Delayed ejaculation can have physiologic causes and can occur after surgery on the genitourinary tract, such as prostatectomy. It may also be associated with Parkinson disease and other neurologic disorders involving the lumbar or sacral sections of the spinal cord. The antihypertensive drug guanethidine monosulfate, methyldopa, the phenothiazines, the tricyclic

drugs, and the selective serotonin reuptake inhibitors (SSRIs), among others, have been implicated in retarded ejaculation. Also, we should differentiate delayed ejaculation from retrograde ejaculation, in which ejaculation occurs but the seminal fluid passes back into the bladder. Retrograde ejaculation always has an organic cause. It can develop after genitourinary surgery, and it is also associated with medications that have anticholinergic adverse effects, such as the phenothiazines.

Other Female Sexual Dysfunction due to a General Medical Condition. Some medical conditions—specifically, endocrine diseases such as hypothyroidism, diabetes mellitus, and primary hyperprolactinemia—can affect a woman's ability to have orgasms. Several drugs also affect some women's capacity to have orgasms (Table 16-12). Antihypertensive medications, CNS stimulants, tricyclic drugs, SSRIs, and, frequently, monoamine oxidase inhibitors (MAOIs) have interfered with female orgasmic capacity. One study of women taking MAOIs, however, found that after 16 to 18 weeks of pharmacotherapy, the adverse effect of the medication disappeared, and the women were able to reexperience orgasms, although they continued taking an undiminished dose of the drug.

[a]The incidence of male erectile disorder associated with the use of tricyclic drugs is low.

[b]Trazodone has been causative in some cases of priapism.

[c]All SSRIs can produce sexual dysfunction, more commonly, in men.

[d]Impairment of sexual function is not a common complication of the use of antipsychotics.

Priapism has occasionally occurred in association with the use of antipsychotics.

eBenzodiazepines have been reported to decrease libido, but in some patients the diminution of anxiety caused by those drugs enhances sexual function.

Substance/Medication-Induced Sexual Dysfunction. We diagnose substance-induced sexual dysfunction when evidence of substance intoxication or withdrawal is apparent from the history, physical examination, or laboratory findings. The disturbance in sexual function must be predominant in the clinical picture. Distressing sexual dysfunction occurs soon after significant substance intoxication or withdrawal, or after exposure to a medication or a change in medication use. Specified substances include alcohol, amphetamines or related substances, cocaine, opioids, sedatives, hypnotics, or anxiolytics, and other or unknown substances.

Abused recreational substances affect sexual function in various ways. In small doses, many substances enhance sexual performance by decreasing inhibition or anxiety or by causing a temporary elevation of mood. With continued use, however, erectile engorgement and orgasmic and ejaculatory capacities become impaired. The abuse of sedatives, anxiolytics, hypnotics, and particularly opiates and opioids nearly always depresses desire. Alcohol may foster the initiation of sexual activity by removing inhibition, but it also impairs performance. Cocaine and amphetamines produce the similar effects. Although no direct evidence indicates that sexual drive is enhanced, users initially have feelings of increased energy and may become sexually active; ultimately, dysfunction occurs. Men usually go through two stages: an experience of prolonged erection without ejaculation, and then a gradual loss of erectile capability.

Patients recovering from substance dependency may need therapy to regain sexual function, partly because of psychological readjustment to a nondependent state. Many substance abusers have always had difficulty with intimate interactions. Others who spent their crucial developmental years under the influence of a substance have missed the experiences that would have enabled them to learn social and sexual skills.

Almost every pharmacologic agent, particularly those used in psychiatry, has been associated with an effect on sexuality. In men, these effects include decreased sex drive, erectile failure, decreased volume of ejaculate, and delayed or retrograde ejaculation. In women, decreased sex drive, decreased

vaginal lubrication, inhibited or delayed orgasm, and decreased or absent vaginal contractions may occur. Drugs may also enhance sexual responses and increase the sex drive, but this is less common than adverse effects.

ANTIPSYCHOTIC DRUGS. Most antipsychotic drugs are dopamine receptor antagonists that also block adrenergic and cholinergic receptors, thus accounting for the adverse sexual effects (Table 16-13). Chlorpromazine and trifluoperazine are potent anticholinergics, and they impair erection and ejaculation. With some drugs, the seminal fluid backs up into the bladder rather than being propelled through the penile urethra. Patients still have a pleasurable sensation, but the orgasm is dry. When urinating after orgasm, the urine may be milky white because it contains the ejaculate. The condition is startling but harmless. Paradoxically, antipsychotics may rarely cause priapism.

Table 16-11
Neurophysiology of Sexual Dysfunction

	DA	5-HT	NE	ACh	Clinical Correlation
Erection	↑	°	α_1, β ↓ ↑	M	Antipsychotics may lead to erectile dysfunction (DA block): DA agonists may lead to enhanced erection and libido; priapism with trazodone (α_1 block); β-blockers may lead to impotence
Ejaculation and orgasm	°	± ↓	α_1 ↑	M	α-Blockers (tricyclic drugs, MAOIs, thioridazine) may lead to impaired ejaculation; 5-HT agents may inhibit orgasm

↑, facilities; ↓, inhibits or decreases; ±, some; ACh, acetylcholine; DA, dopamine; 5-HT, serotonin; M, modulates; NE, norepinephrine; °, minimal.

ANTIDEPRESSANT DRUGS. The tricyclic and tetracyclic antidepressants have anticholinergic effects that interfere with erection and delay ejaculation. Because the anticholinergic effects vary among the cyclic antidepressants, those with the fewest effects (e.g., desipramine) produce the fewest sexual adverse effects.

Some men report increased sensitivity of the glans that is pleasurable, and that does not interfere with erection, although it delays ejaculation. In some cases, however, the tricyclic causes painful ejaculation, perhaps as the result of interference with seminal propulsion caused by interference with, in turn, urethral, prostatic, vas, and epididymal smooth muscle contractions. Clomipramine may increase sex drive in some persons. Selegiline, a selective MAO type B (MAO_B) inhibitor, and bupropion may also increase sex drive,

possibly by dopaminergic activity and increased production of norepinephrine.

Venlafaxine and the SSRIs most often have adverse effects because of the rise in serotonin levels. A lowering of the sex drive and difficulty reaching orgasm occur in both sexes. Cyproheptadine, an antihistamine with antiserotonergic effects, and methylphenidate, with adrenergic effects, may reverse those adverse effects. Trazodone is associated with the rare occurrence of priapism, the symptom of prolonged erection in the absence of sexual stimuli. That symptom appears to result from the α_1-adrenergic antagonism of trazodone.

Table 16-12
Some Pharmacologic Agents Implicated in Inhibited Female Orgasm[a]

Tricyclic antidepressants
  Imipramine (Tofranil)
  Clomipramine (Anafranil)
  Nortriptyline (Aventyl)

Monoamine oxidase inhibitors
  Tranylcypromine (Parnate)
  Phenelzine (Nardil)
  Isocarboxazid (Marplan)

Dopamine receptor antagonists
  Thioridazine (Mellaril)
  Trifluoperazine (Stelazine)

Selective serotonin reuptake inhibitors
  Fluoxetine (Prozac)
  Paroxetine (Paxil)
  Sertraline (Zoloft)
  Fluvoxamine (Luvox)
  Citalopram (Celexa)

[a]The interrelation between female sexual dysfunction and pharmacologic agents has been less extensively evaluated than male reactions. Oral contraceptives are reported to decrease

libido in some women, and some drugs with anticholinergic side effects may impair arousal as well as orgasm. Prolonged use of oral contraceptives may also cause physiologic menopausal-like changes resulting in genito-pelvic pain/penetration disorder. Benzodiazepines have been reported to decrease libido, but in some patients the diminution of anxiety caused by those drugs enhances sexual function. Both increase and decrease in libido have been reported with psychoactive agents. It is difficult to separate those effects from the underlying condition or from improvement of the condition. Sexual dysfunction associated with the use of a drug disappears when use of the drug is discontinued.

The MAOIs affect biogenic amines broadly. Accordingly, they produce impaired erection, delayed or retrograde ejaculation, vaginal dryness, and inhibited orgasm. Tranylcypromine has a paradoxical sexually stimulating effect in some persons, possibly as a result of its amphetamine-like properties.

Mr. W presented with the complaint of inability to achieve orgasm. His problem dated from the time, 18 months previously, when he started fluoxetine. Before that time, he had been able to achieve orgasm through masturbation and coitus with his wife.

Mr. W tried several other SSRIs, as well as venlafaxine, but the side effect of delayed ejaculation persisted. None of the usual antidotes to SSRI-induced anorgasmia proved effective, and the patient then tried antidepressants of other categories. Mr. W was able to respond to bupropion and clonazepam. This combination treated his depression and anxiety, and his delayed ejaculation resolved.

His psychiatrist diagnosed pharmacologically induced delayed ejaculation.

Table 16-13
Diagnostic Issues with Sex and Some Antipsychotic Drugs

Differential diagnosis of drug-induced sexual dysfunction	Problem after drug therapy started or drug overdose
	Problem not situation or partner specific
	Not a lifelong or recurrent

	Fluphenazine
	Molindone
	Risperidone
	Clozapine

Table by R. T. Seagraves, M.D.

Because depression is associated with decreased libido, varying levels of sexual dysfunction and anhedonia are part of the disease process. Some patients report improved sexual functioning as their depression improves because of antidepressant medication. The phenomenon makes evaluating sexual side effects difficult; also, the side effects may disappear with time, perhaps because a biogenic amine homeostatic mechanism comes into play.

LITHIUM. Lithium regulates mood and, in the manic state, may reduce hypersexuality, possibly by a dopamine antagonist activity. Some patients may have impaired erections.

SYMPATHOMIMETICS. Psychostimulants, including amphetamines, methylphenidate, and pemoline, raise the plasma levels of norepinephrine and dopamine. They can increase libido. However, with prolonged use, men may experience a loss of desire and erections.

α-ADRENERGIC AND β-ADRENERGIC RECEPTOR ANTAGONISTS. α-Adrenergic and β-adrenergic receptor antagonists, used in the treatment of hypertension, angina, and certain cardiac arrhythmias, diminish tonic sympathetic nerve outflow from vasomotor centers in the brain. As a result, they can cause impotence, decrease the volume of ejaculate, and produce retrograde ejaculation. They can affect libido in both sexes.

ANTICHOLINERGICS. The anticholinergics block cholinergic receptors and include such drugs as amantadine and benztropine. They produce dryness of the mucous membranes (including those of the vagina) and erectile disorder. However, amantadine may reverse SSRI-induced orgasmic dysfunction through its dopaminergic effect.

ANTIHISTAMINES. Drugs such as diphenhydramine have anticholinergic activity and are mildly hypnotic. They may inhibit sexual function as a result. Cyproheptadine, although an antihistamine, also has potent activity as a serotonin antagonist. It can block the serotonergic sexual adverse effects produced by SSRIs, such as delayed orgasm.

ANTIANXIETY AGENTS. The dominant class of anxiolytics is the benzodiazepines. They act on the γ-aminobutyric acid (GABA) receptors, which are involved in cognition, memory, and motor control. Because benzodiazepines decrease plasma epinephrine concentrations, they diminish anxiety, and as a result, they improve sexual function in persons inhibited by anxiety.

ALCOHOL. Alcohol suppresses CNS activity generally and can produce

erectile disorders in men as a result. Alcohol has a direct gonadal effect that decreases testosterone levels in men; paradoxically, it can produce a slight rise in testosterone levels in women. The latter finding may account for women who report increased libido after drinking small amounts of alcohol. The long-term use of alcohol reduces the ability of the liver to metabolize estrogenic compounds in men, which produces signs of feminization (such as gynecomastia as a result of testicular atrophy).

OPIOIDS. Opioids, such as heroin, have adverse sexual effects, such as erectile failure and decreased libido. The alteration of consciousness may enhance the sexual experience of occasional users.

HALLUCINOGENS. The hallucinogens include lysergic acid diethylamide (LSD), phencyclidine (PCP), psilocybin (from some mushrooms), and mescaline (from peyote cactus). In addition to inducing hallucinations, the drugs cause loss of contact with reality and an expanding and heightening of consciousness. Some users report that the sexual experience is similarly enhanced, but others experience anxiety, delirium, or psychosis, which interfere with sexual function.

CANNABIS. The altered state of consciousness produced by cannabis may enhance sexual pleasure for some persons. Its prolonged use depresses testosterone levels.

BARBITURATES AND SIMILARLY ACTING DRUGS. Barbiturates and similarly acting sedative-hypnotic drugs may enhance sexual responsiveness in persons who are sexually unresponsive as a result of anxiety. They have no direct effect on the sex organs; however, they do produce an alteration in consciousness that some persons find pleasurable. These drugs are subject to abuse, and use can be fatal when combined with alcohol or other CNS depressants.

Methaqualone acquired a reputation as a sexual enhancer, a reputation without basis. It is no longer legally sold in the United States.

Treatment

Before 1970, the most common treatment for sexual dysfunctions was

individual psychotherapy. Classic psychodynamic theory holds that sexual inadequacy has its roots in early developmental conflicts, and the therapist treated the sexual disorder as part of a pervasive emotional disturbance. The symptoms of sexual dysfunctions, however, frequently become secondarily autonomous and continue to persist, even when other problems evolving from the patients' pathology have been resolved. The addition of behavioral techniques is often necessary to cure a sexual problem. Depending on the disorder, medications can be a first-line treatment or an adjunct to therapy.

Somatic Treatments. Biologic treatments, including pharmacotherapy, surgery, and mechanical devices, can treat specific cases of sexual disorder. Most of the recent advances involve male sexual dysfunction.

PHARMACOTHERAPY. Medications for erectile disorder include sildenafil and its congeners (Table 16-14), oral phentolamine, alprostadil, and injectable medications. Other options include papaverine, prostaglandin E1, phentolamine, or some combination of these; and transurethral alprostadil (MUSE).

Sildenafil is a nitric oxide enhancer that facilitates the inflow of blood to the penis necessary for an erection. The drug takes effect about 1 hour after ingestion, and its effect can last up to 4 hours. Sildenafil is not effective in the absence of sexual stimulation. The most common adverse events associated with its use are headaches, flushing, and dyspepsia. Persons taking organic nitrates should not take sildenafil, as the combined action of the two drugs can cause sudden, and sometimes fatal, drops in systemic blood pressure. Sildenafil is not effective in all cases of erectile dysfunction. It fails to produce an erection that is sufficiently rigid for penetration in about 50 percent of men who have had radical prostate surgery or in those with long-standing insulin-dependent diabetes. It is also ineffective in some instances of nerve damage.

A small number of patients developed nonarteritic ischemic optic neuropathy (NAION) soon after using sildenafil. This side effect may be more common in patients with cardiovascular risk factors. Although rare, sildenafil may provoke NAION in individuals with an arteriosclerotic risk profile. Exceedingly rare cases of hearing loss may also occur.

Sildenafil use in women results in vaginal lubrication, but not in increased

desire. Anecdotal reports, however, describe individual women who have experienced intensified excitement with sildenafil.

Oral phentolamine and apomorphine are not FDA approved at present but have proved useful as potency enhancers in men with minimal erectile dysfunction. Phentolamine reduces sympathetic tone and relaxes corporeal smooth muscle. Adverse events include hypotension, tachycardia, and dizziness. Apomorphine effects are mediated by the autonomic nervous system and result in vasodilation that facilitates the inflow of blood to the penis. Adverse events include nausea and sweating.

Table 16-14
Pharmacokinetics of the PDE-5 Inhibitors

	Sildenafil (Viagra)	Vardenafil (Levitra)	Vardenafil ODT (Staxyn)	Tadalafil (Cialis)	Avanafil (Stendra)

In contrast to the oral medications, injectable and transurethral forms of alprostadil act locally on the penis and can produce erections in the absence of sexual stimulation. Alprostadil contains a naturally occurring form of prostaglandin E, a vasodilating agent. Alprostadil may be administered by direct injection into the corpora cavernosa or by intraurethral insertion of a pellet through a cannula. The firm erection produced within 2 to 3 minutes after administration of the drug may last as long as 1 hour. Infrequent and reversible adverse effects of injections include penile bruising and changes in liver function test results. Possible hazardous sequelae exist, including priapism and sclerosis of the small veins of the penis. Users of transurethral alprostadil sometimes complain of burning sensations in the penis.

Two small trials found different topical agents effective in alleviating erectile dysfunction. One cream consists of three vasoactive substances

absorbed through the skin: aminophylline, isosorbide dinitrate, and co-dergocrine mesylate, which is a mixture of ergot alkaloids. The other is a gel containing alprostadil and an additional ingredient, which temporarily makes the outer layer of the skin more permeable.

Also, a cream incorporating alprostadil exists for female sexual arousal disorder. Vaginally applied phentolamine mesylate, an α-receptor antagonist, can increase vasocongestion and a subjective sense of arousal. Flibanserin is also FDA-approved to increase desire in women.

The pharmacologic treatments described in the preceding text are useful in the treatment of arousal dysfunction of various causes: neurogenic, arterial insufficiency, venous leakage, psychogenic, and mixed. When coupled with insight-oriented or behavioral sex therapy, the use of medications can reverse psychogenic arousal disorder that is resistant to psychotherapy alone, the ultimate goal being pharmacologically unassisted sexual functioning.

Other Pharmacologic Agents. Numerous other pharmacologic agents have been used to treat various sexual disorders. Intravenous methohexital sodium assists with desensitization therapy. Antianxiety agents may have some application for tense patients. The side effects of antidepressants, in particular the SSRIs and tricyclic drugs, have been used to prolong the sexual response in patients with premature ejaculation. This approach is particularly useful in patients who are refractory to behavioral techniques. Topical anesthetic creams may help decrease the intravaginal ejaculation latency time (IELT) in cases of premature ejaculation. Antidepressants can help patients who are phobic of sex and in those with posttraumatic stress disorder following rape. Trazodone is an antidepressant that improves nocturnal erections. We should always weigh the risks of taking such medications against their possible benefits. Bromocriptine treats hyperprolactinemia, which is frequently associated with hypogonadism and any associated sexual dysfunction. In such patients, it is necessary to rule out pituitary tumors.

Several substances have popular standing as aphrodisiacs; for example, ginseng root and yohimbine. Studies, however, have not confirmed any aphrodisiac properties. Yohimbine, an α-receptor antagonist, may cause dilation of the penile artery; however, the American Urologic Association does not recommend its use to treat organic erectile dysfunction. Many

recreational drugs, including cocaine, amphetamines, alcohol, and cannabis, are considered enhancers of sexual performance. Although they may provide the user with an initial benefit because of their tranquilizing, disinhibiting, or mood-elevating effects, consistent or prolonged use of any of these substances impairs sexual functioning.

Dopaminergic agents may increase libido and improve sex function. Those drugs include L-dopa, a dopamine precursor, and bromocriptine, a dopamine agonist. The antidepressant bupropion has dopaminergic effects and has increased sex drive in some patients. Selegiline, an MAOI, is selective for MAO_B and is dopaminergic. It improves sexual functioning in older persons.

HORMONE THERAPY. Androgens increase the sex drive in women and men with low testosterone concentrations. Women may experience virilizing effects, some of which are irreversible (e.g., deepening of the voice). In men, prolonged use of androgens produces hypertension and prostatic enlargement. Testosterone is most effective when given parenterally; however, effective oral and transdermal preparations are available.

Women who use estrogens for replacement therapy or contraception may report decreased libido; in such cases, a combined preparation of estrogen and testosterone may help. Estrogen itself prevents thinning of the vaginal mucous membrane and facilitates lubrication. Several forms of locally delivered estrogen—vaginal rings, vaginal creams, and vaginal tablets—provide alternate administration routes to treat women with arousal problems or genital atrophy. Because tablets, creams, and rings do not significantly increase circulating estrogen levels, we should consider these devices for patients with breast cancer with arousal problems.

ANTIANDROGENS AND ANTIESTROGENS. Estrogens and progesterone are antiandrogens that have been used to treat compulsive sexual behavior in men, usually in sex offenders. Clomiphene and tamoxifen are both antiestrogens, and both stimulate gonadotropin-releasing hormone (GnRH) secretion and increase testosterone concentrations, thereby increasing libido. Women treated for breast cancer with tamoxifen report an increased libido. However, tamoxifen may cause uterine cancer.

MECHANICAL TREATMENT APPROACHES. Male patients with

arteriosclerosis (especially of the distal aorta, known as Leriche syndrome), may lose their erection during active pelvic thrusting. The need for increased blood in the gluteal muscles and others served by the ilial or hypogastric arteries takes blood away (steals) from the pudendal artery and, thus, interferes with penile blood flow. They can obtain relief by decreasing pelvic thrusting, which is also aided by the woman's superior coital position.

VACUUM PUMP. Vacuum pumps are mechanical devices that patients without a vascular disease can use to obtain erections. The vacuum draws blood to the penis and kept there by a ring at the base of the penis. This device has no adverse effects, but it is cumbersome, and partners must be willing to accept its use. Some women complain that the penis is redder and cooler than a natural erection or find the process objectionable.

   A similar device, called EROS, has been developed to create clitoral erections in women. EROS is a small suction cup that fits over the clitoral region and draws blood into the clitoris. Studies have reported its success in treating female sexual arousal disorder. Vibrators used to stimulate the clitoral area have been successful in treating anorgasmic women.

OTHER SOMATIC TREATMENTS

Male Prostheses. Surgical treatment is rarely indicated, but penile prosthetic devices are available for men with inadequate erectile responses who are resistant to other treatment methods or who have medically caused deficiencies. The two main types of prostheses are (1) a semi-rigid rod prosthesis that produces a permanent erection that can be positioned close to the body for concealment and (2) an inflatable type that is implanted with its reservoir and pump for inflation and deflation. The latter type can mimic normal physiologic functioning.

Vascular Surgery. When vascular insufficiency is present due to atherosclerosis or other blockages, bypass surgery of penile arteries may help in selected cases.

Psychosocial Treatments

DUAL-SEX THERAPY. The theoretical basis of dual-sex therapy is the concept of the marital unit or dyad as the object of therapy; the approach represented the

significant advance in the diagnosis and treatment of sexual disorders in the 20th century. The methodology was originated and developed by Masters and Johnson. In dual-sex therapy, when a dysfunctional person is in a relationship, the couple must be treated. Because both are involved in a sexually distressing situation, both must participate in the therapy program. The sexual problem often reflects other areas of disharmony or misunderstanding in the relationship so that the entire relationship is treated, with emphasis on the sexual functioning of the partners.

The keystone of the program is the roundtable session in which a male and female therapy team clarifies, discusses, and works through problems with the couple. The four-way sessions require active participation by the patients. Therapists and patients discuss the psychological and physiologic aspects of sexual functioning, and therapists have an educative attitude. Therapists suggest specific sexual activities for the couple to follow in the privacy of their home. The therapy aims to establish or reestablish communication within the partner unit. Sex is emphasized as a natural function that flourishes in the appropriate domestic climate, and improved communication is encouraged toward that end. In a variation of this therapy that has proved useful, one therapist may treat the couple. Treatment is short term and is behaviorally oriented. The therapists attempt to reflect the situation as they see it, rather than interpret underlying dynamics. An undistorted picture of the relationship presented by the therapists often corrects the myopic, narrow view held by each partner. This new perspective can interrupt the couple's destructive pattern of relating and can encourage improved, more effective communication. Specific exercises are prescribed for the couple to treat their particular problems. Sexual inadequacy often involves a lack of information, misinformation, and performance fear. Therefore, the therapist prohibits any sexual play other than what was prescribed. Beginning exercises usually focus on heightening sensory awareness to touch, sight, sound, and smell. Initially, the therapist also prohibits intercourse, and the couple learns to give and receive bodily pleasure without the pressure of performance or penetration. At the same time, they learn how to communicate nonverbally in a mutually satisfactory way, and they learn that sexual foreplay is an enjoyable alternative to intercourse and orgasm.

During the sensate focus exercises, the couple receives much reinforcement to reduce anxiety. They can use fantasies to distract them from

obsessive concerns about performance (spectatoring). They should consider the needs of both the dysfunctional partner and the nondysfunctional partner. If either partner becomes sexually excited by the exercises, the other is encouraged to bring them to orgasm by manual or oral means. Open communication and the expression of mutual needs are encouraged. Resistances, such as claims of fatigue or not enough time to complete the exercises, are common and must be dealt with by the therapists. Issues of body image, fear of being touched, and difficulty touching oneself arise frequently. Eventually, the therapy allows genital stimulation in addition to general body stimulation. The couple should sequentially to try various positions for intercourse, without necessarily completing the act, and to use varieties of stimulating techniques before they proceed with intercourse.

Psychotherapy sessions follow each new exercise period, and problems and satisfactions, both sexual and in other areas of the couple's lives, are discussed. The therapist reviews specific instructions and introduces new exercises geared to the individual couple's progress. Gradually, the couple gains confidence and learns to communicate, verbally and sexually. Dual-sex therapy is most effective when sexual dysfunction exists apart from other psychopathology. The more difficult treatment cases involve couples with severe marital discord. Desire disorders are particularly challenging to treat. They require more extended and intensive therapy than some other disorders, and their outcomes vary greatly.

SPECIFIC TECHNIQUES AND EXERCISES. Various techniques can treat various sexual dysfunctions. In cases of vaginismus, a woman is advised to dilate her vaginal opening with her fingers or with size-graduated dilators. Dilators can also treat cases of dyspareunia. Sometimes, specially trained physiotherapists can assist the treatment by helping the patients to relax their perineal muscles.

In cases of premature ejaculation, an exercise known as the squeeze technique can raise the threshold of penile excitability. In this exercise, the man or the woman stimulates the erect penis until feeling the earliest sensations of impending ejaculation. At this point, the partner forcefully squeezes the coronal ridge of the glans, diminishing the erection and inhibiting ejaculation. The exercise program eventually raises the threshold of the sensation of ejaculatory inevitability and allows the man to focus on the sensations of arousal without anxiety and develop confidence in his sexual

performance. A variant of the exercise is the stop-start technique developed by James H. Semans, in which the woman stops all stimulation of the penis when the man first senses an impending ejaculation without squeezing. Research has shown that the presence or absence of circumcision has no bearing on a man's ejaculatory control; the glans is equally sensitive in the two states. Sex therapy has been most successful in the treatment of premature ejaculation.

A man with a sexual desire disorder or male erectile disorder can masturbate to prove that full erection and ejaculation are possible. Delayed ejaculation is managed initially by extravaginal ejaculation and then by gradual vaginal entry after stimulation to a point near ejaculation. Most importantly, the early exercises forbid ejaculation to remove the pressure to climax and allow the man to immerse himself in sexual pleasuring.

In cases of lifelong female orgasmic disorder, the woman is directed to masturbate, sometimes using a vibrator. The shaft of the clitoris is the masturbatory site most preferred by women, and orgasm depends on adequate clitoral stimulation. An area on the anterior wall of the vagina exists in some women as a site of sexual excitation, known as the *G-spot,* but reports of an ejaculatory phenomenon at orgasm in women following the stimulation of the G-spot is only anecdotal.

BEHAVIOR THERAPY. Behavioral approaches were initially designed for the treatment of phobias but are now used to treat other problems as well. Behavior therapists assume that the patient learns sexual dysfunction as maladaptive behavior, which causes them to fear sexual interaction. Using traditional techniques, therapists set up a hierarchy of anxiety-provoking situations, ranging from least threatening (e.g., the thought of kissing) to most threatening (e.g., the thought of penile penetration). The behavior therapist enables the patient to master the anxiety through a standard program of systematic desensitization, which inhibits the learned anxious response by encouraging behaviors antithetical to anxiety. The patient first deals with the least anxiety-producing situation in fantasy and progresses by steps to the most anxiety-producing situation. Medication, hypnosis, and specialized training in deep muscle relaxation can help with the initial mastery of anxiety.

Assertiveness training can help teach patients to express sexual needs

openly and without fear. The patient receives exercises in assertiveness, given in conjunction with sex therapy, and they are encouraged to make sexual requests and to refuse to comply with requests perceived as unreasonable. Sexual exercises may be prescribed for patients to perform at home, and the therapist helps the patient to establish a hierarchy, starting with those activities that have proved most pleasurable and successful in the past.

One treatment variation involves the participation of the patient's sexual partner in the desensitization program. The partner, rather than the therapist, presents items of increasing stimulation value to the patient. A cooperative partner is necessary to help the patient carry gains made during treatment sessions to sexual activity at home.

Couples who regularly practice assigned exercises appear to have a much higher likelihood of success than do more resistant couples or those whose interaction involves sadomasochistic or depressive features or mechanisms of blame and projection. Attitude flexibility is also a favorable prognostic factor. Overall, younger couples tend to complete sex therapy more often than older couples. Couples whose interactional difficulties center on their sex problems, such as inhibition, frustration, or fear of performance failure, are also likely to respond well to therapy.

MINDFULNESS. Mindfulness is a cognitive technique that has been helpful in the treatment of sexual dysfunction. The patient focuses on the moment and maintains an awareness of sensations—visual, tactile, auditory, and olfactory—that he or she experiences in the moment. The aim is to distract the patient from "spectatoring" (watching him or herself) and center the person on the sensations that lead to arousal or orgasm. Hopefully, this shift in focus allows patients to become immersed in the pleasure of the experience and remove themselves from self-judgment and performance anxiety.

GROUP THERAPY. Group therapy helps to examine both intrapsychic and interpersonal problems in patients with sexual disorders. A therapy group provides a strong support system for a patient who feels ashamed, anxious, or guilty about a particular sexual problem. It is a useful forum in which to counteract sexual myths, correct misconceptions, and provide accurate information about sexual anatomy, physiology, and varieties of behavior.

One can organize the groups in several ways. Members may all share the

same problem, such as premature ejaculation; members may all be of the same sex with different sexual problems, or groups may be composed of both men and women who are experiencing a variety of sexual problems. Group therapy can be an adjunct to other forms of therapy or the prime mode of treatment. Groups organized to treat a particular dysfunction are usually behavioral in approach.

Groups composed of married couples with sexual dysfunctions are also useful. A group provides the opportunity to gather accurate information, offers consensual validation of individual preferences, and enhances self-esteem and self-acceptance. Techniques, such as role-playing and psychodrama, may be used in treatment. Such groups are not indicated for couples when one partner is uncooperative, when a patient has a severe depressive disorder or psychosis, when a patient finds explicit sexual audiovisual material repugnant, or when a patient fears or dislikes groups.

HYPNOTHERAPY. Hypnotherapists focus specifically on the anxiety-producing situation—that is, the sexual interaction that results in dysfunction. The successful use of hypnosis enables patients to gain control over the symptom that has been lowering self-esteem and disrupting psychological homeostasis. The patient's cooperation is first obtained and encouraged during a series of nonhypnotic sessions with the therapist. Those discussions permit the development of a secure doctor–patient relationship, a sense of physical and psychological comfort on the part of the patient, and the establishment of mutually desired treatment goals. During this time, the therapist assesses the patient's capacity for the trance experience. The nonhypnotic sessions also permit the clinician to take a psychiatric history and perform a mental status examination before beginning hypnotherapy. The focus of treatment is on symptom removal and attitude alteration. The patient develops alternative means of dealing with the anxiety-provoking situation, the sexual encounter.

Also, the therapist teaches relaxation techniques for use before sexual relations. With these methods to alleviate anxiety, the physiologic responses to sexual stimulation can more readily result in pleasurable excitation and discharge. The therapy helps to remove psychological impediments to vaginal lubrication, erection, and orgasms so that normal sexual functioning ensues. Hypnosis may be added to a basic individual psychotherapy program to accelerate the effects of psychotherapeutic intervention.

ANALYTICALLY ORIENTED SEX THERAPY. Some therapists combine sex therapy with psychodynamic psychotherapy. The therapy occurs over a more extended period than usual, which allows learning or relearning of sexual satisfaction under the realities of patients' day-to-day lives. The addition of psychodynamic conceptualizations to behavioral techniques used to treat sexual dysfunctions allows the treatment of patients with sexual disorders associated with other psychopathology.

The material and dynamics that emerge in patients in analytically oriented sex therapy are the same as those in psychoanalytic therapy, such as dreams, fear of punishment, aggressive feelings, difficulty trusting a partner, fear of intimacy, oedipal feelings, and fear of genital mutilation. The combined approach of analytically oriented sex therapy is used by the general psychiatrist, who carefully judges the optimal timing of sex therapy and the ability of patients to tolerate the directive approach that focuses on their sexual difficulties.

PARAPHILIC DISORDERS

Paraphilias or perversions are sexual stimuli or acts that are deviations from normal sexual behaviors but are necessary for some persons to experience arousal and orgasm. DSM-5 only considers this a disorder when a person has acted on the fantasy or impulse, or if the fantasies or impulses lead to significant distress. Individuals with paraphilic interests can experience sexual pleasure, but they do not respond to stimuli that are typically considered erotic. The paraphiliac person's sexuality is mainly restricted to specific deviant stimuli or acts. Persons who occasionally experiment with paraphilic behavior (e.g., infrequent episode of bondage or dressing in costumes), but can respond to more typical erotic stimuli, do not have paraphilic disorders.

Paraphilic disorders can range from nearly normal behavior to behavior that is destructive or hurtful only to a person's self or to a person's self and partner, and finally to behavior that is deemed destructive or threatening to the community at large. DSM-5 lists pedophilia, frotteurism, voyeurism, exhibitionism, sexual sadism, sexual masochism, fetishism, and transvestism with explicit diagnostic criteria because of their threat to others or because they are relatively common paraphilias. Many other paraphilias exist.

A particular fantasy with its unconscious and conscious components is the pathognomonic element of the paraphilia, with sexual arousal and orgasm being associated phenomena that *reinforce the fantasy or impulse.* The influence of these fantasies and their behavioral manifestations often extend beyond the sexual sphere to pervade people's lives.

The primary functions of human sexual behavior are to assist in bonding, to create mutual pleasure in cooperation with a partner, to express and enhance love between two persons, and to procreate. Paraphilic disorders entail divergent behaviors in that those acts involve aggression, victimization, and extreme one-sidedness. The behaviors exclude or harm others and disrupt the potential for bonding between persons. Moreover, paraphilic sexual scripts often serve other vital psychic functions. They may assuage anxiety, bind aggression, or stabilize identity.

The Clinical Presentation and Diagnosis

In DSM-5, the criteria for paraphilic disorder require the patient to experience intense and recurrent arousal from their deviant fantasy for at least 6 months and to either act on the paraphilic impulse or experience significant distress as a result of the impulse. The fantasy distressing the patient contains unusual sexual material that is relatively fixed and shows only minor variations. Arousal and orgasm depend on the mental elaboration, if not the behavioral playing out of the fantasy. Sexual activity is ritualized or stereotyped and makes use of degraded, reduced, or dehumanized objects.

Exhibitionism

Exhibitionism is the recurrent urge to expose the genitals to a stranger or an unsuspecting person. Sexual excitement occurs in anticipation of the exposure, and orgasm is brought about by masturbation during or after the event. In almost 100 percent of cases, those with exhibitionism are men exposing themselves to women. The dynamic of men with exhibitionism is to assert their masculinity by showing their penises and by watching the victims' reactions—fright, surprise, and disgust. In other related paraphilias, the central themes involve derivatives of looking or showing.

A substance-abusing professional was finally able to attain sobriety at age

33 years. With this accomplishment, he met a woman and got married, began to work steadily for the first time in his life, and was able to impregnate his new wife. His preferred sexual activity had been masturbation in semi-public places. The patient had a strong sense that his mother had always thought him to be inadequate, did not like to spend time with him, and constantly made negative comparisons between him and his "all-boy" younger brother. He recalled several times when his father had tried to explain his mother's antipathy: "It is just one of those things, son: your mother does not seem to like you." Without substance abuse, he gave up his exhibitionism, but he quickly developed sexual incapacity with his wife and became "addicted" to phone sex. (Courtesy of Stephen B. Levine, M.D.)

Specifiers added to exhibitionistic disorder by DSM-5 differentiate between arousal from exposing genitals to prepubertal children, to physically mature individuals, or both (Table 16-15).

Fetishism

In fetishism, the sexual focus is on objects (e.g., shoes, gloves, pantyhose, and stockings) that are intimately associated with the human body, or on nongenital body parts. The latter focus is sometimes called *partialism*. DSM-5 applies the diagnosis of fetishistic disorder to partialism and attaches the following specifiers to fetishistic disorder: body part(s); nonliving parts; other (Table 16-16). The particular fetish used is linked to someone closely involved with a patient during childhood and has a quality associated with this loved, needed, or even traumatizing person. Usually, the disorder begins by adolescence, although the fetish may begin in childhood. Once established, the disorder tends to be chronic.

Course Specifiers	**In full remission:** no symptoms or distress for ≥5 yr

The patient may direct sexual activity at the fetish itself (e.g., masturbation with or into a shoe), or may incorporate the fetish into sexual intercourse (e.g., the demand that high-heeled shoes be worn). The disorder is almost exclusively found in men. Learning theorists believe that the object was associated with sexual stimulation at an early age.

A 50-year-old man entered treatment with a chief complaint of erectile disorder experienced primarily with his wife. He was suffering from a moderate depression that related to both his marital issues and business problems. He had no erectile problems with women he picked up in bars or knew and arranged to meet in bars, partly because where he lived, smoking was allowed in bars. The woman's act of smoking a cigarette was necessary to his sexual arousal. His family history included an alcoholic mother and an emotionally abusive father who was a chain smoker. On family car trips, the father would smoke, with all the car windows up. If the patient complained of feeling nauseous, the father would tell him to "shut up." He recalled being very attracted to a Sunday school teacher who smoked when he was six years old. He first smoked when he was 13, sneaking and hiding behind his house. His first cigarette was one he stole from a pack on his mother's night table.

Frotteurism

Frotteurism is usually characterized by a man's rubbing his penis against the buttocks or other body parts of a fully clothed woman to achieve orgasm (Table 16-17). At other times, he may use his hands to rub an unsuspecting victim. The acts usually occur in crowded places, particularly in subways and buses. Those with frotteurism are passive and isolated, and frottage is often their only source of sexual gratification. The expression of aggression in this paraphilia is readily apparent.

Pedophilia

Pedophilia involves recurrent intense sexual urges toward, or arousal by, children. Per DSM-5, the child must be under 14 years old, and the patient must be at least 16 years old and at least five years older than the victims.

Most child molestations involve genital fondling or oral sex. Vaginal or anal penetration of children infrequently occurs, except in cases of incest. Although most child victims coming to public attention are girls, this finding may be a product of the referral process. Offenders report that when they touch a child, most (60 percent) of the victims are boys. This figure is in sharp contrast to the figure for nontouching victimization of children, such as window peeping and exhibitionism; 99 percent of all such cases occur against girls. DSM-5 includes criteria to specify the genders of the patient's target, and Table 16-18 compares the criteria for this disorder.

Of persons with pedophilia, 95 percent are heterosexual, and 50 percent have consumed alcohol to excess at the time of the incident. Many perpetrators concomitantly or have previously committed exhibitionism, voyeurism, or rape.

Incest is related to pedophilia by the frequent selection of an immature child as a sex object, the subtle or overt element of coercion, and occasionally the preferential nature of the adult–child liaison.

> **Frotteurism**

DSM-5	ICD-10

Name	Frotteuristic Disorder	Other disorders of sexual preference *Frotteurism*
Duration	≥6 mo	
Symptoms	Sexual arousal/fantasies/urges/behaviors that result from touching/rubbing against a nonconsenting individual	Sexual arousal from rubbing against people in public spaces
Psychosocial Impact	Marked distress and/or psychosocial impairment	
Severity Specifiers	**In a controlled environment** (lives in institution/other controlled environment)	
Course Specifiers	**In full remission:** no symptoms or distress for ≥5 yr	
Comments		This category also includes *Necrophilia* in addition to behaviors such as making obscene phone calls, engaging in sexual activity with animals, an

...use of strangulation for sexual excitement.

A 62-year-old married janitor had worked as a fourth-grade school teacher for 26 years before he transferred school districts, and several years later mysteriously lost his second job. He was referred for help after his family discovered that he had repeatedly fondled the genitals of his 4- and 6-year-old granddaughters. A father of five who had not had sex with his wife for 30 years after strenuously objecting to her cigarette smoking, he was generous, helpful, and cooperative with his children and grandchildren. Intellectually slow, he preferred comic books and had a charming manner of playing with young children "like he was one himself." By his estimate, he had touched the buttocks and genitals of at least 300 girl students, thinking only of how they did not know what he was doing because he was affectionate, and they were too young to realize what was happening. He loved the anticipation and excitement of this behavior. His teaching career ended when parents complained to a principal. The principal discovered that the man had lost his last job for the same reason. (Courtesy of Stephen B. Levine, M.D.)

Sexual Masochism

Masochism takes its name from the 19th-century novelist Sacher-Masoch, whose characters derived sexual pleasure from being abused and dominated by women. According to the DSM-5, persons with sexual masochism have a recurrent preoccupation with sexual urges and fantasies involving the act of being humiliated, beaten, bound, or otherwise made to suffer (Table 16-19). The diagnosis includes asphyxiophilia or autoerotic asphyxiation as a subtype. It is the practice of achieving or heightening sexual arousal with restriction of breathing. Sexual masochistic practices are more common among men than among women. Persons with sexual masochism may have had childhood experiences that convinced them that pain is a prerequisite for sexual pleasure. About 30 percent of those with sexual masochism also have

sadistic fantasies. Moral masochism involves a need to suffer but does not include sexual fantasies.

Sexual Masochism

	DSM-5	ICD-10
Name	Sexual Masochism Disorder	Sadomasochis
Duration	≥6 mo	
Symptoms	Sexual arousal/fantasies/urges/behaviors that result from being humiliated/hit/bound/made to suffer	Preference for sexual activity to include: Bondage Infliction of pain or humiliation (as the recipient)
Psychosocial Impact	Marked distress and/or psychosocial impairment	
Symptom Specifiers	**With asphyxiophilia:** arousal from restriction of breathing	
Severity Specifiers	**In a controlled environment:** lives in institution/other controlled environment	
Course Specifiers	**In full remission:** no symptoms or distress for ≥5 yr	
Comments		ICD combined masochism

	and sadism into one diagnosis

A 27-year-old woman presented for a job interview. She was accompanied by a man whom she introduced, saying, "This is my lover." When asked about this, the woman said that her companion had ordered her to bring him and introduce him in that way. She further explained that she was part of a group that utilized sadomasochistic techniques in their sexual play.

Sexual Sadism

Sexual sadism is recurrent and intense sexual arousal from the physical and psychological suffering of another person. The name is from the Marquis de Sade, an 18th-century French author who wrote novels detailing violent sexual acts against women, and was himself imprisoned for such acts. A person must have experienced these feelings for at least 6 months and must have either acted on sadistic fantasies or experienced significant distress as a result of these fantasies to receive a diagnosis of sexual sadism disorder (Table 16-20).

The onset of the disorder is usually before the age of 18 years, and most persons with sexual sadism are male. Sexual sadism likely derives from early abusive life experiences. However, there is little data about how the disorder develops. Sexual sadism is related to rape, although rape is more aptly considered an expression of power. Some sadistic rapists, however, kill their victims after having sex (so-called lust murders). In many cases, these persons have underlying schizophrenia, and they may also suffer from a dissociative disorder or have a history of head trauma.

Voyeurism

Voyeurism, also known as *scopophilia,* is the recurrent preoccupation with fantasies and acts that involve observing unsuspecting persons who are naked or engaged in grooming or sexual activity (Table 16-21). Masturbation to orgasm usually accompanies or follows the event. The first voyeuristic act

usually occurs during childhood, and the paraphilia is most common in men. When persons with voyeurism are apprehended, the charge is usually loitering.

Transvestism

Transvestism, formerly called transvestic fetishism, is described as fantasies and sexual urges to dress in opposite gender clothing as a means of arousal and as an adjunct to masturbation or coitus. DSM also has various specifiers depending on the exact nature of the fantasy, and Table 16-22 compares the criteria for this disorder.

Table 16-20

Transvestism typically begins in childhood or early adolescence. With time, some men want to dress and live permanently as women. Very rarely, women want to dress and live as men. DSM-5 considers this to be a combination of transvestic disorder and gender dysphoria. Usually, a person wears more than one article of opposite sex clothing; frequently, this involves an entire wardrobe. When a man with transvestism cross-dresses, the appearance of femininity may be striking, although not usually to the degree found in transsexualism. When not dressed in women's clothes, men with transvestism may be hypermasculine in appearance and occupation. Cross-dressing can range from solitary, guilt-ridden behaviors to ego-syntonic, social membership in a subculture.

The overt clinical syndrome of transvestism may begin in latency but is more often seen around pubescence or in adolescence. Frank dressing in opposite-sex clothing usually does not begin until the person is relatively independent of their parents.

Other Specified Paraphilic Disorder

DSM-5 includes a generalized category for paraphilias that cause distress but do not fit into one of the previous categories. We describe some examples of these next.

In some cases, we may not wish to specify the exact paraphilia, such as when we do not yet have enough information; in these cases, we would diagnose an unspecified paraphilic disorder.

Telephone and Computer Scatologia. Telephone scatologia involves

obscene phone calling to an unsuspecting recipient. Tension and arousal begin in anticipation of phoning; the recipient of the call listens while the telephoner (usually male) verbally exposes his preoccupations or induces her to talk about her sexual activity. The conversation is accompanied by masturbation.

Persons also use interactive computer networks, sometimes compulsively, to send obscene messages by electronic mail and to transmit sexually explicit messages and video images. Because of the anonymity of the users in chat rooms who use aliases, on-line or computer sex (cybersex) allows some persons to play the role of the opposite sex ("genderbending"), which represents an alternative method of expressing transvestic or other fantasies. A danger of on-line cybersex is that pedophiles often make contact with children or adolescents who lure children into meeting and then molest them. Many on-line contacts develop into off-line liaisons. Although some persons report that the off-line encounters develop into meaningful relationships, most such meetings are filled with disappointment and disillusionment, as the fantasized person fails to meet the unconscious expectations of the ideal partner. In other situations, when adults meet, rape or even homicide may occur.

Severity Specifiers	**In a controlled environment:** lives in institution/other controlled environment	
Course Specifiers	**In full remission:** no symptoms or distress for ≥5 yr	

Necrophilia. Necrophilia is an obsession with obtaining sexual gratification from cadavers. Most persons with this disorder find corpses in morgues, but some may rob graves or even murder to satisfy their sexual urges. In the few cases studied, those with necrophilia believed that they were inflicting the greatest conceivable humiliation on their lifeless victims. Some experts consider this a type of psychosis.

Partialism. Persons with the disorder of partialism concentrate their sexual activity on one part of the body to the exclusion of all others. Mouth–genital contacts—such as cunnilingus (oral contact with a woman's external genitals), fellatio (oral contact with the penis), and anilingus (oral contact with the anus)—is typically associated with foreplay. However, when a person uses these activities as the sole source of sexual gratification and cannot have or refuses to have coitus, a paraphilia exists. It is also known as *oralism.* As described earlier, transvestism is a type of partialism but differs in that the focus is not on a sexual organ.

Zoophilia. In zoophilia, persons incorporate animals into arousal fantasies

or sexual activities, including intercourse, masturbation, and oral–genital contact. Zoophilia, as an organized paraphilia, is rare. For many persons, animals are the primary source of relatedness, so it is not surprising that some may use a broad variety of domestic animals sensually or sexually.

Sexual relations with animals may occasionally be an outgrowth of availability or convenience, especially in parts of the world where rigid convention precludes premarital sexuality and in situations of enforced isolation. Because masturbation is also available in such situations, however, a predilection for animal contact is probably present in opportunistic zoophilia.

Coprophilia, Urophilia, and Klismaphilia. Coprophilia is sexual pleasure associated with the desire to defecate on a partner, to be defecated on, or to eat feces (coprophagia). A variant is the compulsive utterance of obscene words (coprolalia). Urophilia, a form of urethral eroticism, is an interest in sexual pleasure associated with the desire to urinate on a partner or to be urinated on. The disorder may be associated with masturbatory techniques involving the insertion of foreign objects into the urethra for sexual stimulation. Similarly, klismaphilia is the use of enemas for sexual stimulation.

Hypoxyphilia. Hypoxyphilia is the desire to achieve an altered state of consciousness secondary to hypoxia while experiencing orgasm. Persons may use a drug (e.g., a volatile nitrite or nitrous oxide) to produce hypoxia. Autoerotic asphyxiation is related and is a form of sexual masochism.

Differential Diagnosis

Clinicians must differentiate a paraphilia from an experimental act that is not recurrent or compulsive and done for its novelty. Paraphilic activity most likely begins during adolescence. Some paraphilias (especially the bizarre types) are associated with other mental disorders, such as schizophrenia. Brain diseases can also release perverse impulses.

Course and Prognosis

The difficulty in controlling or curing paraphilic disorders rests in the fact

that it is hard for people to give up sexual pleasure with no assurance that alternative approaches will be as sexually gratifying. The prognosis is poor when it begins at an early age, and when it occurs frequently. Also, a lack of guilt is a bad predictor of outcome, as is a substance use disorder. The course and the prognosis are better when patients also engage in regular sexual activity. It may also be better when patients self-refer than are forced to present for legal reasons.

Treatment

There are five types of psychiatric interventions used to treat persons with paraphilic disorder: external control, reduction of sexual drives, treatment of comorbid conditions (e.g., depression or anxiety), cognitive-behavioral therapy, and dynamic psychotherapy.

Prison is an external control mechanism for sexual crimes that usually does not contain a treatment element. When victimization occurs in a family or work setting, the external control comes from informing supervisors, peers, or other adult family members of the problem and advising them about eliminating opportunities for the perpetrator to act on urges.

Drug therapy, including antipsychotic or antidepressant medication, is indicated for the treatment of schizophrenia or depressive disorders if the paraphilia is associated with these disorders. Antiandrogens, such as cyproterone acetate in Europe and medroxyprogesterone acetate (Depo-Provera) in the United States, may reduce the drive to behave sexually by decreasing serum testosterone levels to subnormal concentrations. Serotonergic agents, such as fluoxetine, have been used with limited success in some patients with paraphilia.

Cognitive-behavioral therapy can disrupt learned paraphilic patterns and modify behavior to make it socially acceptable. The interventions include social skills training, sex education, cognitive restructuring (confronting and destroying the rationalizations used to support the victimization of others), and development of victim empathy. The therapist can also teach the patient imaginal desensitization and relaxation technique. The patient can also learn what triggers the paraphilic impulse so that they can avoid these stimuli. In modified aversive behavior rehearsal, the therapist videotapes the perpetrators acting out their paraphilia with a mannequin. Then the therapist

or a peer group may confront the patient with questions about feelings, thoughts, motives associated with the act and repeatedly try to correct cognitive distortions and point out the lack of victim empathy to the patient.

Insight-oriented psychotherapy is a long-standing treatment approach. Patients have the opportunity to understand their dynamics and the events that caused the paraphilia to develop. In particular, they become aware of the daily events that cause them to act on their impulses (e.g., a real or fantasized rejection). Treatment helps them deal more effectively with life stresses and enhances their capacity to relate to a life partner. Also, psychotherapy allows patients to regain self-esteem, which in turn allows them to approach a partner in a more normal sexual manner. Sex therapy is an appropriate adjunct to the treatment of patients with specific sexual dysfunctions when they attempt nondeviant sexual activities.

Good treatment predictors include the presence of a single paraphilia, normal intelligence, the absence of substance abuse, the absence of nonsexual antisocial personality traits, and the presence of a successful adult attachment. Paraphilic disorders, however, remain significant treatment challenges even under these circumstances.

Epidemiology

Paraphilias are rare, but the insistent, repetitive nature of the disorders results in a high frequency of such acts. Thus, many people are victims of persons with paraphilic disorders. It may be that the prevalence of paraphilias is much higher than that found in clinical care, given the large commercial market in paraphilic pornography and paraphernalia. We do not know how many consumers of these materials act on their fantasies or cannot respond to typical erotic stimuli.

Among legally identified cases of paraphilic disorders, pedophilia is most common. Of all children, 10 to 20 percent have been molested by age 18. Because the act involves a child, it has gotten more attention than some other paraphilic disorders. Persons with exhibitionism who publicly display themselves to young children are also commonly apprehended. Those with voyeurism may be apprehended, but their risk is not considerable. Of adult females, 20 percent have been the targets of persons with exhibitionism and voyeurism. Sexual masochism and sexual sadism are underrepresented in any

prevalence estimates. Sexual sadism usually comes to attention only in sensational cases of rape, brutality, and lust murder. The excretory paraphilic disorders rarely come to clinical attention, as it usually takes place between consenting adults or between a sex worker and client. Persons with fetishism rarely become entangled in the legal system. Those with transvestism may be arrested occasionally for disturbing the peace or on other misdemeanor charges if they are men dressed in women's clothes, but an arrest is more common among those with gender identity disorders. Zoophilia, as an actual paraphilic disorder, is rare (Table 16-23).

As usually defined, the paraphilias seem to be mostly male conditions. Fetishism almost always occurs in men. More than 50 percent of all paraphilias have their onset before age 18. Patients with paraphilia frequently have three to five paraphilias, either concurrently or at different times in their lives. This pattern of occurrence is especially the case with exhibitionism, fetishism, sexual masochism, sexual sadism, transvestic fetishism, voyeurism, and zoophilia (see Table 16-23). The occurrence of paraphilic behavior peaks between ages 15 and 25 and gradually declines. DSM-5 suggests the paraphilia designation be reserved for those ages 18 and older to avoid pathologizing healthy sexual curiosity and occasional experimentation in adolescence. In men older than 50, criminal paraphilic acts are rare. Those that occur are practiced in isolation or with a cooperative partner.

Table 16-23
Frequency of Paraphilic Acts Committed by Patients with Paraphilia Seeking Outpatient Treatment

Etiology

Psychosocial Factors. Many paraphilias can be traced back to childhood experiences that condition or socialize children into committing a paraphilic act. The first shared sexual experience can be significant in that regard. Molestation as a child can predispose a person to accept continued abuse as an adult or, conversely, to become an abuser of others. Also, early experiences of abuse that are not explicitly sexual, such as spanking, enemas, or verbal humiliation, can be sexualized by a child and can form the basis for a paraphilia. Such experiences can result in the development of an *eroticized child.*

A 34-year-old man presented for the treatment of an erectile disorder. He was frequently unable to obtain an erection sufficient for coitus with his wife. The problem disappeared whenever she was willing to act out his bondage fantasy and tie him up with ropes, a scenario he intensely desired. He explained that he felt free to be sexual when tied up because it reassured him that he could move vigorously and not hurt the woman. Also, he gave a history of being tied up "in fun" when he was a child by a babysitter who would then tickle him until he begged her to stop.

The onset of paraphilic acts can result from persons' modeling their behavior on the behavior of others who have carried out paraphilic acts,

mimicking sexual behavior depicted in the media, or recalling emotionally laden events from the past, such as their molestation. Learning theory indicates that because the fantasizing of paraphilic interests begins at an early age and because children are likely to hide their fantasies from others (who might discourage them), the use and misuse of paraphilic fantasies and urges continue uninhibited until late in life. Only then do persons begin to realize that such paraphilic interests and urges are inconsistent with societal norms. By that time, however, the repetitive use of such fantasies has become ingrained, and sexual thoughts and behaviors have become associated with or conditioned to paraphilic fantasies.

In the classic psychoanalytic model, persons with a paraphilia have failed to complete the normal developmental process toward sexual adjustment, but new psychoanalytic approaches have modified the model. What distinguishes one paraphilia from another is the method chosen by a person (usually male) to cope with the anxiety caused by the threat of castration by the father and separation from the mother. However bizarre its manifestation, the resulting behavior provides an outlet for the sexual and aggressive drives that would otherwise channel into normal sexual behavior.

Biologic Factors. Several studies have identified abnormal biologic findings in persons with paraphilias. None has used random samples of such persons; instead, they have extensively investigated patients with paraphilia at large medical centers. Among these patients, those with positive physical findings included 74 percent with abnormal hormone levels, 27 percent with hard or soft neurologic signs, 24 percent with chromosomal abnormalities, 9 percent with seizures, 9 percent with dyslexia, 4 percent with abnormal electroencephalography (EEG) studies, 4 percent with major mental disorders, and 4 percent with an intellectual disorder. It is not clear whether these abnormalities are causally related or incidental to the paraphilia.

Psychophysiological tests can measure the penile volumetric size in response to paraphilic and nonparaphilic stimuli. The procedures may be of use in diagnosis and treatment but are of questionable diagnostic validity because some men can suppress their erectile responses.

SEX ADDICTION AND COMPULSIVITY

The concept of sex addiction developed over the last two decades to refer to persons who compulsively seek out sexual experiences and whose behavior becomes impaired if they are unable to gratify their sexual impulses. This concept derives from the model of substance addiction or such addictive behaviors as gambling. Addiction implies psychological dependence, physical dependence, and the presence of a withdrawal syndrome if the substance or behavior is not available.

DSM-5 does not contain the diagnosis of sex addiction or compulsive sexuality, and the concept remains controversial. Nevertheless, the phenomenon of a person whose life revolves around sex-seeking behavior and activities, who spends an excessive amount of time in such behavior, and who often tries to stop such behavior but is unable to do so is well known to clinicians. Such persons show repeated and increasingly frequent attempts to have a sexual experience, deprivation of which gives rise to symptoms of distress. When encountering such a story, this should alert the clinician to find an underlying cause for the behavior.

Sex addicts cannot control their sexual impulses, which can involve the entire spectrum of sexual fantasy or behavior. Eventually, the need for sexual activity increases, and the person's behavior is mainly motivated by the persistent desire to experience the sex act. The history usually reveals a long-standing pattern of such behavior, which the person repeatedly has tried to stop, but without success. Although a patient may have feelings of guilt and remorse after the act, these feelings do not suffice to prevent its recurrence. The patient may report that their need to act out is most severe during stressful periods or when angry, depressed, anxious, or otherwise dysphoric. Most acts culminate in sexual orgasm. Eventually, the sexual activity interferes with the person's social, vocational, or marital life, which begins to deteriorate. Table 16-24 lists the signs of sexual addiction.

Table 16-24
Signs of Sexual Addiction

1. Out-of-control behavior

2. Severe adverse consequences (medical, legal, interpersonal) due to sexual behavior

3. Persistent pursuit of self-destructive or high-risk sexual behavior

4. Repeated attempts to limit or stop sexual behavior

5. Sexual obsession and fantasy as a primary coping mechanism

6. The need for increasing amounts of sexual activity

7. Severe mood changes related to sexual activity (e.g., depression, euphoria)

8. Inordinate amount of time spent in obtaining sex, being sexual, or recovering from sexual experience

9. Interference of sexual behavior in social, occupational, or recreational activities

Some men who appear to be hypersexual, as manifested by their need to have many sexual encounters or conquests, use their sexual activities to mask deep feelings of inferiority, this is sometimes called *Don Juanism*. Some are unconsciously attracted to other men, which they deny by compulsive sexual contact with women. After having sex, most Don Juans are no longer interested in the woman. The condition is also called *satyriasis.*

In a woman, a similar condition is called nymphomania. Of the few scientific studies of the condition, those patients who were studied usually have had one or more sexual disorders, often including female orgasmic disorder. The woman often has an intense fear of losing love and, through her actions, attempts to satisfy her dependence needs rather than gratify her sexual impulses.

Comorbidity

Many sex addicts have an associated psychiatric disorder. The comorbid diagnosis may be challenging to recognize, given that the addictive disorder produces considerable stress and anxiety on its own. Most common are substance use disorders (up to 80 percent in some studies), which not only complicates the task of diagnosis, but also complicates treatment.

Treatment

Self-help groups based on the 12-step concept used in Alcoholics Anonymous (AA) have been used successfully with many sex addicts. They include such groups as Sexaholics Anonymous (SA), Sex and Love Addicts Anonymous (SLAA), and Sex Addicts Anonymous (SAA). The groups differ in that some are for men or women, or married persons or couples. All advocate some abstinence from either the addictive behavior or sex in general. Should a substance use disorder also be present, the patient often requires referral to AA or Narcotics Anonymous (NA) as well. Patients may enter an inpatient treatment unit when they lack sufficient motivation to control their behavior on an outpatient basis or pose a danger to themselves or others. Also, severe medical or psychiatric symptoms may require careful supervision and treatment best carried out in a hospital.

A 42-year-old married businessman with two children was considered a model of virtue in his community. He was active in his church and on the boards of several charitable organizations. He was living a secret life, however, and would lie to his wife, telling her that he was at a board meeting when he was visiting massage parlors for paid sex. He eventually was engaging in the behavior four to five times a day, and although he tried to quit many times, he was unable to do so. He knew that he was harming himself by putting his reputation and marriage at risk.

The patient presented himself to the psychiatric emergency room, stating that he would prefer to be dead rather than continue the behavior described. He was admitted with a diagnosis of major depressive disorder and started on a daily dose of 20 mg of fluoxetine. He also received 100 mg of medroxyprogesterone intramuscularly once a day. His need to masturbate diminished markedly and ceased entirely on the third hospital day, as did his mental preoccupation with sex. His clinicians discontinued the medroxyprogesterone on the sixth day and discharged him. He continued to take fluoxetine, enrolled in a local SA group, and entered individual and couples psychotherapy. His addictive behavior eventually stopped, he was having satisfactory sexual relations with his wife, and he was no longer suicidal or depressed.

Pharmacotherapy. Certain medications may be of use in treating sex

addiction, however, because of their specific effects on reducing the sex drive. SSRIs reduce libido in some persons. Compulsive masturbation is an example of a behavioral pattern that may benefit from such medication. Medroxyprogesterone acetate diminishes libido in men and, thus, makes it easier to control sexually addictive behavior.

There is little information on the use of antiandrogens in women to control hypersexuality; however, they might be of benefit. Antiandrogenic agents (e.g., cyproterone acetate) are not available in the United States, but in Europe, they have had varying success. Antiandrogenic medications remain controversial, and some clinicians see it as chemical castration.

Psychotherapy. Insight-oriented psychotherapy may help patients understand the dynamics of their behavioral patterns. Supportive psychotherapy can help repair the interpersonal, social, or occupational damage that occurs. Cognitive behavioral therapy helps the patient recognize dysphoric states that precipitate sexual acting out. Marital therapy or couples therapy can help the patient regain self-esteem. It is also helpful to the partners who need assistance in understanding the disease and dealing with their complex reactions to the situation. Finally, psychotherapy may help in the treatment of any associated psychiatric disorder.

NORMAL SEXUALITY

Sexuality is determined by anatomy, physiology, the culture in which a person lives, relationships with others, and developmental experiences throughout the life cycle. It includes the perception of being male or female and private thoughts and fantasies as well as behavior. To the average person, sexual attraction to another person and the passion and love that follow are deeply associated with feelings of intimate happiness.

Healthy sexual behavior brings pleasure to oneself and one's partner and involves stimulation of the primary sex organs, including coitus; it is devoid of inappropriate feelings of guilt or anxiety and is not compulsive. Societal understanding of what defines normal sexual behavior is inconstant and varies from era to era, reflecting the cultural mores of the time.

Terms

Sexuality and personality cannot be separated as they are related; hence the term *psychosexual,* to describe personality development and functioning as affected by sexuality. The term *psychosexual* applies to more than sexual feelings and behavior, and it is not synonymous with *libido* in the Freudian sense.

Childhood Sexuality

Before Freud described the effects of childhood experiences on the personalities of adults, the universality of sexual activity and sexual learning in children was unrecognized. Most sexual learning experiences in childhood occur without the parents' knowledge, but awareness of a child's sex does influence parental behavior. Male infants, for instance, tend to be handled more vigorously, and female infants cuddled more. Fathers spend more time with their infant sons than with their daughters, and they also tend to be more aware of their sons' adolescent concerns than of their daughters' anxieties. Boys are more likely than girls to be physically disciplined. A child's sex affects parental tolerance for aggression and reinforcement or extinction of activity and intellectual, aesthetic, and athletic interests.

Observation of children reveals that genital play in infants is part of healthy development. According to Harry Harlow, interaction with mothers and peers is necessary for the development of active adult sexual behavior in monkeys, a finding that has relevance to the socialization of children. During a critical period in development, infants are especially susceptible to certain stimuli; later, they may be immune to these stimuli. We do not entirely understand the detailed relation of critical periods to psychosexual development; Freud's stages of psychosexual development—oral, anal, phallic, latent, and genital—presumably provide a broad framework.

Psychosexual Factors

Sexuality depends on four interrelated psychosexual factors: sexual identity, gender identity, sexual orientation, and sexual behavior. These factors affect personality, growth, development, and functioning. Sexuality is something more than physical sex, coital or noncoital, and something less than all behaviors directed toward attaining pleasure.

Sexual Identity, Gender Identity, and Sexual Orientation

Sexual identity is the pattern of a person's biologic sexual characteristics: chromosomes, external genitalia, internal genitalia, hormonal composition, gonads, and secondary sex characteristics. In healthy development, these characteristics form a cohesive pattern that leaves a person in no doubt about his or her sex. Gender identity is a person's sense of maleness or femaleness. Sexual identity and gender identity are interactive. Genetic influences and hormones affect behavior, and the environment affects hormonal production and gene expression (Table 16-25).

Sexual Identity. Modern embryologic studies have shown that all mammalian embryos, whether genetically male (XY genotype) or genetically female (XX genotype), are anatomically female during the early stages of fetal life. Differentiation of the male from the female results from the action of fetal androgens; the action begins about the sixth week of embryonic life and finishes by the end of the third month. Recent research has focused on the possible roles of critical genes in fetal sexual development. A testis develops because of SRY and SOX9 action, and an ovary develops in the absence of such action. DAX1 plays a part in the fetal development of both sexes, and WNT4 action is needed for the development of the müllerian ducts in the female fetus. Other studies have explained the effects of fetal hormones on the masculinization or feminization of the brain. In animals, prenatal hormonal stimulation of the brain is necessary for male and female reproductive and copulatory behavior. The fetus is also vulnerable to exogenously administered androgens during that period. For instance, if a pregnant woman receives sufficient exogenous androgens, her female fetus that possesses ovaries can develop external genitalia resembling those of a male fetus.

In the past, newborns with ambiguous genitalia were assigned their sexual identity at birth. The theory underlying this action was that parents and child would feel less confusion and that the child would accept the assigned sex and more easily develop a stable sense of being male or female. Although this worked for some children, others developed a gender identity at odds with their assigned sex. For example, an infant designated female at birth could instead feel male throughout childhood, and more emphatically at

puberty. In some cases, this conflict led to depression and even suicide. Current practice usually allows the child to develop with the ambiguity, which permits a sense of gender identity to evolve as the child grows. The gender identity is then more congruent with the child's emotional sense of maleness or femaleness. Ideally, the family receives support from a medical team composed of a pediatrician, an endocrinologist, and a psychiatrist throughout this developmental process.

Table 16-25
Classification of Intersexual Disorders[a]

Syndrome	Description
Virilizing adrenal hyperplasia (adrenogenital syndrome)	Results from excess androgens in fetus with XX genotype; most common female intersex disorder; associated with enlarged clitoris, fused labia, hirsutism in adolescence
Turner syndrome	Results from absence of second female sex chromosome (XO); associated with web neck, dwarfism, cubitus valgus; no sex hormones produced; infertile
Klinefelter syndrome	Genotype is XXY; male habitus present with small penis and rudimentary testes because of low androgen production; weak libido; usually assigned as male
Androgen insensitivity syndrome (testicular-feminizing syndrome)	Congenital X-linked recessive disorder that results in inability of tissues to respond to androgens; external genitals look female and cryptorchid testes present; in extreme form patient has breasts, normal external genitals, short blind vagina, and absence of pubic and axillary hair

Enzymatic defects in XY genotype (e.g., 5-α-reductase deficiency, 17-hydroxy-steroid deficiency)	Congenital interruption in production of testosterone that produces ambiguous genitals and female habitus
Hermaphroditism	True hermaphrodite is rare and characterized by both testes and ovaries in same person (may be 46 XX or 46 XY)
Pseudohermaphroditism	Usually the result of endocrine or enzymatic defect (e.g., adrenal hyperplasia) in persons with normal chromosomes; female pseudohermaphrodites have masculine-looking genitals but are XX; male pseudohermaphrodites have rudimentary testes and external genitals and are XY

[a]Intersexual disorders include a variety of syndromes that produce persons with gross anatomical or physiologic aspects of the opposite sex.

Gender Identity. In infants with an unambiguous sexual identity, almost everyone has a firm conviction that "I am male" or "I am female" by 2 to 3 years of age. However, even if maleness and femaleness develop typically, persons must still develop a sense of masculinity or femininity.

Gender identity, according to Robert Stoller, "connotes psychological aspects of behavior related to masculinity and femininity." Stoller considers gender social and sex biologic: "Most often, the two are relatively congruent, that is, males tend to be manly and females womanly." Nevertheless, sex and gender can develop in conflicting or even opposite ways. Gender identity results from an almost infinite series of cues derived from experiences with family members, teachers, friends, and coworkers, and from cultural phenomena. Physical characteristics derived from a person's biologic sex— such as physique, body shape, and physical dimensions—interrelate with an intricate system of stimuli, including rewards and punishment and parental

gender labels, to establish gender identity.

Thus, the formation of gender identity arises from parental and cultural attitudes, the infant's external genitalia, and genetic influence, which is physiologically active by the sixth week of fetal life. Although family, cultural, and biological influences may complicate the establishment of a sense of masculinity or femininity, persons usually develop a relatively secure sense of identification with their biologic sex—a stable gender identity.

GENDER ROLE. Related to, and in part derived from, gender identity is gender role behavior. John Money and Anke Ehrhardt described gender role behavior as all those things that a person says or does to disclose himself or herself as having the status of boy or man, girl or woman, respectively. A gender role is not established at birth, but builds gradually through (1) experiences encountered and transacted through casual and unplanned learning, (2) explicit instruction and inculcation, and (3) spontaneously putting two and two together to sometimes make four and sometimes five. The usual outcome is a congruence of gender identity and gender roles. Although biologic attributes are significant, the primary factor in achieving the role appropriate to a person's sex is learning.

Research on sex differences in children's behavior reveals more psychological similarities than differences. Girls, however, are found to be less susceptible to tantrums after the age of 18 months than are boys, and boys generally are more physically and verbally aggressive than are girls from age two onward. Little girls and little boys are similarly active, but boys are more easily stimulated to sudden bursts of activity when they are in groups. Some researchers speculate that, although aggression is a learned behavior, male hormones may have sensitized boys' neural organizations to absorb these lessons more readily than do girls.

Persons' gender roles can seem to be opposed to their gender identities. They may identify with their sex and yet adopt the dress, hairstyle, or other characteristics of the opposite sex. Alternatively, they may identify with the opposite sex and yet for expediency adopt many behavioral characteristics of their sex. A further discussion of gender issues appears in Chapter 17.

Sexual Orientation. Sexual orientation describes the object of a person's

sexual impulses: opposite sex, same-sex, or both sexes. A group of people have defined themselves as "asexual" and assert this as a positive identity. Some researchers believe this lack of attraction to any object is a manifestation of a desire disorder. Other people wish not to define their sexual orientation at all and avoid labels. Still, others describe themselves as polysexual or pansexual.

The Biology of Sexual Behavior

The Brain

CORTEX. The cortex is involved both in controlling sexual impulses and in processing sexual stimuli that may lead to sexual activity. In studies of young men, some areas of the brain are more active during sexual stimulation than others. These include the orbitofrontal cortex, which is involved in emotions; the left anterior cingulate cortex, which is involved in hormone control and sexual arousal; and the right caudate nucleus, whose activity is a factor in whether sexual activity follows arousal.

LIMBIC SYSTEM. In all mammals, the limbic system is directly involved with elements of sexual functioning. Chemical or electrical stimulation of the lower part of the septum and the contiguous preoptic area, the fimbria of the hippocampus, the mammillary bodies, and the anterior thalamic nuclei have all elicited penile erections.

Studies of the brain in women have revealed that those areas activated by emotions of fear or anxiety are notably quiescent when the woman experiences an orgasm.

BRAINSTEM. Brainstem sites exert inhibitory and excitatory control over spinal sexual reflexes. The nucleus paragigantocellularis projects directly to pelvic efferent neurons in the lumbosacral spinal cord, apparently causing them to secrete serotonin, which is known to inhibit orgasms. The lumbosacral cord also receives projections from other serotonergic nuclei in the brainstem.

BRAIN NEUROTRANSMITTERS. Many neurotransmitters, including dopamine, epinephrine, norepinephrine, and serotonin, are produced in the brain and affect sexual function. For example, an increase in dopamine likely increases

libido. Serotonin, produced in the upper pons and midbrain, exerts an inhibitory effect on sexual function. Oxytocin is released with orgasm and may reinforce pleasurable activities.

Spinal Cord. Ultimately, sexual arousal and climax are organized at the spinal level. Afferents from the pudendal, pelvic, and hypogastric nerves convey the sensory stimuli related to sexual function. Several separate experiments suggest that spinal neurons mediate sexual reflexes in the central gray region of the lumbosacral segments.

Physiologic Responses. Sexual response is a psychophysiological experience. Both psychological and physical stimuli trigger arousal and an aroused person experiences both physiologic and emotional tension. With orgasm, usually, subjective perception of a peak of physical reaction and release occurs along with a feeling of well-being. Psychosexual development, psychological attitudes toward sexuality, and attitudes toward one's sexual partner are directly involved with, and affect, the physiology of human sexual response.

Usually, men and women experience a sequence of physiologic responses to sexual stimulation. In the first detailed description of these responses, Masters and Johnson observed that the physiologic process involves increasing levels of vasocongestion and myotonia (tumescence) and the subsequent release of the vascular activity and muscle tone as a result of orgasm (detumescence). Tables 16-26 and 16-27 describe the physiologic male and female sexual response cycles. It is important to remember that the sequence of responses can overlap and fluctuate. A sexual fantasy or the desire to have sex frequently precedes the physiologic responses of excitement, orgasm, and resolution, particularly in the male. Also, a person's subjective experiences are as relevant to sexual satisfaction as the objective physiologic response. Figures 16-1 and 16-2 illustrate several possible patterns in the phases of the male sexual response and female sexual response, respectively.

Hormones and Sexual Behavior. In general, substances that increase dopamine levels in the brain increase desire, whereas substances that augment serotonin decrease desire. Testosterone increases libido in both men

and women, although estrogen is a crucial factor in the lubrication involved in female arousal and may increase sensitivity in the woman to stimulation. Recent studies indicate that estrogen is also a factor in the male sexual response and that a decrease in estrogen in the middle-aged male results in higher fat accumulation just as it does in women. Progesterone mildly depresses desire in men and women as do excessive prolactin and cortisol. Oxytocin is involved in pleasurable sensations during sex and increases in men and women after orgasm.

Gender Differences in Desire and Erotic Stimuli

Sexual impulses and desire exist in men and women. In measuring desire by the frequency of spontaneous sexual thoughts, interest in participating in sexual activity, and alertness to sexual cues, males generally possess a higher baseline level of desire than do women, which may be biologically determined. Motivations for having sex, other than desire, exist in both men and women but seem to be more varied and prevalent in women. In women, they may include a wish to reinforce the pair bond, the need for a feeling of closeness, a way of preventing the man from straying, or a desire to please the partner.

Although explicit sexual fantasies are common to both sexes, the external stimuli for the fantasies frequently differ for men and women. Many men respond sexually to visual stimuli of nude or barely dressed women. Women report responding sexually to romantic stories such as a demonstrative hero whose passion for the heroine impels him toward a lifetime commitment to her. A complicating factor is that a woman's subjective sense of arousal is not always congruent with her physiologic state of arousal. Her sense of excitement may reflect a readiness to be aroused rather than physiologic lubrication. Conversely, she may experience signs of arousal, including vaginal lubrication, without being aware of them. This situation rarely occurs in men.

Masturbation

Masturbation is usually a standard precursor of object-related sexual behavior. To paraphrase MS Patton, no other form of sexual activity is more discussed, more condemned, and more universally practiced. Research by

Kinsey into the prevalence of masturbation indicated that nearly all men and three-fourths of all women masturbate sometime during their lives.

Longitudinal studies of development show that sexual self-stimulation is common in infancy and childhood. Just as infants learn to explore the functions of their fingers and mouths, they learn to do the same with their genitalia. At about 15 to 19 months of age, both sexes begin genital self-stimulation. Pleasurable sensations result from any gentle touch to the genital region. Those sensations, coupled with the ordinary desire for exploration of the body, produce a healthy interest in masturbatory pleasure at that time. Children also develop an increased interest in the genitalia of others—parents, children, and even animals. As youngsters acquire playmates, the curiosity about their own and others' genitalia motivates episodes of exhibitionism or genital exploration. Such experiences, unless blocked by guilty fear, contribute to continued pleasure from sexual stimulation.

With the approach of puberty, the upsurge of sex hormones, and the development of secondary sex characteristics, sexual curiosity intensifies, and masturbation increases. Adolescents are physically capable of coitus and orgasm but are usually inhibited by social restraints. The dual and often conflicting pressures of establishing their sexual identities and controlling their sexual impulses produce a strong physiologic sexual tension in teenagers that demands release, and masturbation is a healthy way to reduce sexual tensions. In general, males learn to masturbate to orgasm earlier than females and masturbate more frequently. An important emotional difference between the adolescent and the youngster of earlier years is the presence of coital fantasies during masturbation in the adolescent. These fantasies are an essential adjunct to the development of sexual identity; in the comparative safety of the imagination, the adolescent learns to perform the adult sex role. This autoerotic activity continues into the young adult years when coitus becomes more common.

Table 16-26
Male Sexual Response Cycle^a

Organ	Excitement Phase	Orgasmic Phase	Resolution Phase

	Lasts several minutes to several hours; heightened excitement before orgasm, 30 s to 3 min	3–5 s	10–15 min; if no orgasm, ½–1 day
Skin	Just before orgasm: sexual flush inconsistently appears; maculopapular rash originates on abdomen and spreads to anterior chest wall, face, and neck and can include shoulders and forearms	Well-developed flush	Flush disappears in reverse order of appearance; inconsistently appearing film of perspiration on soles of feet and palms of hands
Penis	Erection in 10–30 s caused by vasocongestion of erectile bodies of corpus cavernosa of shaft; loss of erection may occur with introduction of asexual stimulus, loud	Ejaculation; emission phase marked by three to four 0.8-s contractions of vas, seminal vesicles, prostate; ejaculation proper	Erection: partial involution in 5–10 s with variable refractory period; full detumescence in 5–30 min

	noise; with heightened excitement, size of glands and diameter of penile shaft increase further	marked by 0.8-s contractions of urethra and ejaculatory spurt of 12–20 in at age 18, decreasing with age to seepage at 70	
Scrotum and testes	Tightening and lifting of scrotal sac and elevation of testes; with heightened excitement, 50% increase in size of testes over unstimulated state and flattening against perineum, signaling impending ejaculation	No change	Decrease to baseline size because of loss of vasocongestion; testicular and scrotal descent within 5–30 min after orgasm; involution may take several hours if no orgasmic release takes place
Cowper glands	2–3 drops of mucoid fluid that contain	No change	No change

	viable sperm are secreted during heightened excitement		
Other	Breasts: inconsistent nipple erection with heightened excitement before orgasm Myotonia: semispastic contractions of facial, abdominal, and intercostal muscles Tachycardia: up to 175 beats a minute Blood pressure: rise in systolic 20–80 mm; in diastolic 10–40 mm Respiration: increased	Loss of voluntary muscular control Rectum: rhythmical contractions of sphincter Heart rate: up to 180 beats a minute Blood pressure: up to 40–100 mm systolic; 20–50 mm diastolic Respiration: up to 40 respirations a minute	Return to baseline state in 5–10 min A refractory period follows orgasm, during which time the male cannot be rearoused to erection and is unresponsive to stimulation. The length of the refractory period is age and situation dependent

[a]A desire phase consisting of sex fantasies and desire to have sex precedes excitement phase.

Table by Virginia Sadock, M.D.

Couples in a sexual relationship do not abandon masturbation entirely. When coitus is unsatisfactory or is unavailable because of illness or the

absence of the partner, self-stimulation often serves an adaptive purpose, combining sensual pleasure and tension release.

Kinsey reported that when women masturbate, most prefer clitoral stimulation. Masters and Johnson stated that women prefer the shaft of the clitoris to the glans because the glans is hypersensitive to intense stimulation. Most men masturbate by vigorously stroking the penile shaft and glans.

Several studies found that in men, orgasm from masturbation raised the serum prostate-specific antigen (PSA) significantly. Male patients scheduled for PSA tests should be advised not to masturbate (or have coitus) for at least seven days before the examination.

Moral taboos against masturbation have generated myths that masturbation causes mental illness or decreased sexual potency. No scientific evidence supports such claims. Masturbation is a psychopathological symptom only when it becomes a compulsion beyond a person's willful control. Then, it is a symptom of emotional disturbance, not because it is sexual, but because it is compulsive. Masturbation is probably a universal aspect of psychosexual development, and, in most cases, it is adaptive.

Coitus

The first coitus is a rite of passage for both men and women. In the United States, most people have experienced coitus by young adulthood. In a study of people ages 18 to 59, over 95 percent had included coitus in their last sexual interaction.

Table 16-27
Female Sexual Response Cycle*a*

Organ	Excitement Phase	Orgasmic Phase	Resolution Phase
	Lasts several minutes to several hours; heightened excitement before orgasm,	3–15 seconds	10–15 minutes; if no orgasm, ½–1 day

	30 s to 3 min		
Skin	Just before orgasm: sexual flush inconsistently appears; maculopapular rash originates on abdomen and spreads to anterior chest wall, face, and neck; can include shoulders and forearms	Well-developed flush	Flush disappears in reverse order of appearance; inconsistently appearing film of perspiration on soles of feet and palms of hands
Breasts	Nipple erection in two-thirds of women, venous congestion and areolar enlargement; size increases to one-fourth over normal	Breasts may become tremulous	Return to normal in about 30 min
Clitoris	Enlargement in diameter of glans and shaft; just before orgasm, shaft retracts into prepuce	No change	Shaft returns to normal position in 5–10 s; detumescence in 5–30 min; if no orgasm, detumescence

			takes several hours
Labia majora	Nullipara: elevate and flatten against perineum	No change	Nullipara: decrease to normal size in 1–2 min
	Multipara: congestion and edema		Multipara: decrease to normal size in 10–15 min
Labia minora	Size increased two to three times over normal; change to pink, red, deep red before orgasm	Contractions of proximal labia minora	Return to normal within 5 min
Vagina	Color change to dark purple; vaginal transudate appears 10–30 s after arousal; elongation and ballooning of vagina; lower third of vagina constricts before orgasm	3–15 contractions of lower third of vagina at intervals of 0.8 s	Ejaculate forms seminal pool in upper two-thirds of vagina; congestion disappears in seconds or, if no orgasm, in 20–30 min
Uterus	Ascends into false pelvis; labor-like contractions	Contractions throughout orgasm	Contractions cease, and uterus descends to

	begin in heightened excitement just before orgasm		normal position
Other	Myotonia A few drops of mucoid secretion from Bartholin glands during heightened excitement Cervix swells slightly and is passively elevated with uterus	Loss of voluntary muscular control Rectum: rhythmical contractions of sphincter Hyperventilation and tachycardia	Return to baseline status in seconds to minutes Cervix color and size return to normal, and cervix descends into seminal pool

[a]A desire phase consisting of sex fantasies and desire to have sex may precede or overlap with the excitement phase.

Table by Virginia Sadock, M.D.

The young man experiencing intercourse for the first time is vulnerable in his pride and self-esteem. Cultural myths still perpetuate the idea that he should be able to have an erection with no, or little, stimulation, and that he should have an effortless mastery over the situation, even though it is an act that he has never before experienced. Cultural pressure on the woman with her first coitus reflects remaining cultural ambivalence about her loss of virginity, despite the current era of sexual liberality. This reality is illustrated by a survey that found only 50 percent of young women use contraception during their first coitus, and of that 50 percent, an even smaller number use it consistently after that. Young women with a history of masturbation are more likely to approach intercourse with positive anticipation and confidence.

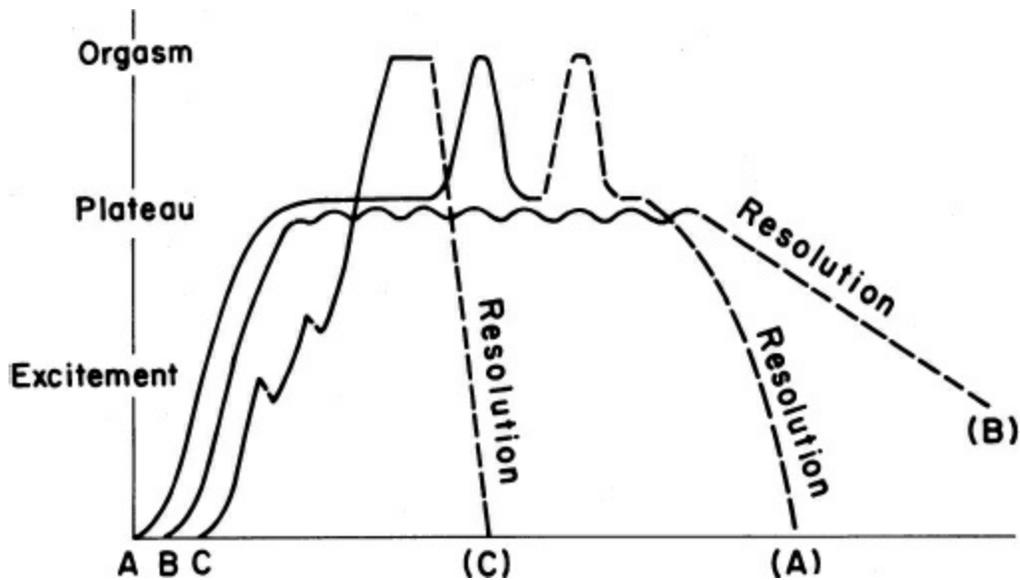

FIGURE 16-2

Female sexual response. An individual woman may experience any of these three patterns (**A, B,** or **C**) during a particular sexual experience. (From Walker JI, ed. *Essentials of Clinical Psychiatry*, Philadelphia, PA: JB Lippincott; 1985:276. with permission.)

In the last decade, coitus has also been part of the sexual repertoire of elderly adults, due to the development of sildenafil type drugs, which

facilitate erections in men, and hormonally enhanced creams or hormonal pills, which counteract vaginal atrophy in postmenopausal women. Before the development of these drugs, many elderly adults enjoyed gratifying sex play, exclusive of coitus.

Gender Dysphoria, Gender Identity, and Related Conditions

INTRODUCTION

In this chapter, we discuss gender identity and associated disorders. We start with gender identity and related conditions.

Gender identity refers to the sense one has of being male or female, which corresponds most often to the person's anatomical sex. Persons with gender dysphoria express their discontent with their assigned sex as a desire to have the body of the other sex or to be regarded socially as a person of the other sex.

The term gender dysphoria appears as a diagnosis for the first time in DSM-5 to refer to those persons with a marked incongruence between their experienced or expressed gender and the one assigned at birth. It was known as gender identity disorder in the previous edition of DSM.

In ICD-10, gender identity issues appear under Disorders of Adult Behavior and Personality in the category Gender Identity Disorders and include five diagnoses: transsexualism, dual-role transvestic, gender identity disorder of childhood, other gender identity disorders, and gender identity disorder, unspecified.

The ICD Working Group on the Classification of Sexual Disorders and Sexual Health is recommending that for ICD-11, gender identity concerns be moved from the psychological sections and is considering options that would list these concerns in a separate chapter, as medical diagnoses, or as part of a new chapter on sexual health and sexual disorders.

The term *transgender* is a general term used to refer to those who identify

with a gender different from the one they were born with (sometimes referred to as their assigned gender). Transgender people are a diverse group: those who want to have the body of another sex known as transsexuals; those who feel they are between genders, of both genders, or neither gender known as genderqueer; and those who wear clothing traditionally associated with another gender, but who maintain a gender identity that is the same as their birth-assigned gender known as cross-dressers. Contrary to popular belief, most transgender people do not have genital surgery. Some do not desire it, and others who do may be unable to afford it. Transgender people may be of any sexual orientation. For example, a transgender man, assigned female at birth, may identify as gay (attracted to other men), straight (attracted to women), or bisexual (attracted to both men and women).

DIAGNOSIS AND CLINICAL FEATURES

Children

The DSM-5 defines gender dysphoria in children as incongruence between expressed and assigned gender, with the most critical criterion being a desire to be another gender or insistence that one is another gender. By emphasizing the importance of the child's self-perception, the creators of the diagnosis attempt to limit its use to those children who clearly state their wishes to be another gender, rather than encompassing a broader group of children who might be considered by adults to be gender nonconforming. However, a child's behavior may also lead to this diagnosis. Table 17-1 compares the approaches to diagnosing gender dysphoria or gender identity disorder.

Many children with gender dysphoria prefer clothing typical of another gender, preferentially choose playmates of another gender, enjoy games and toys associated with another gender, and take on the roles of another gender during play. In gender dysphoria, these social characteristics accompany other traits that are less likely to be socially influenced, such as a strong desire to be the other gender, dislike of one's sexual anatomy, or desire for primary or secondary sexual characteristics of the desired gender. Children may express a desire to have different genitals, state that their genitals are going to change, or urinate in the position (standing or sitting) typical of another gender. Also, although the caregivers may be distressed, it is the

child who must feel clinically significant distress or impairment because of the condition for there to be a diagnosis.

Adolescents and Adults

Adolescents and adults diagnosed with gender dysphoria must also show an incongruence between expressed and assigned gender. Also, they must meet at least two of six criteria, half of which are related to their current (or in the cases of early adolescents, future) secondary sex characteristics or desired secondary sex characteristics. Other criteria include a strong desire to be another gender, be treated as another gender, or the belief that one has the typical feelings and reactions of another gender (see Table 17-1).

In practice, most adults who present to mental health practitioners with reports of gender-related concerns are aware of the concept of transgender identity. They may be interested in therapy to explore gender issues. They may also make contact to request a letter recommending hormone treatment or surgery. The cultural trope of being "trapped in the wrong body" does not apply to all, or even most, people who identify as transgender, so clinicians should be aware of using open and affirming approaches, taking language cues from their patients.

The DSM-5 criteria are noticeably open to the idea that some people do not fit into the traditional gender binary and might desire to be alternative genders, such as genderqueer. As with children, adolescents and adults should be personally distressed or impaired by their feelings. The adolescent and adult criteria also contain a posttransition specifier, which is for people living in their affirmed genders. For this specifier, they have to have had at least one medical or surgical procedure or be preparing for one.

Table 17-1
Gender Dysphoria

	DSM-5	ICD-10
Name	Gender Dysphoria	Gender Identity Disorder (Several Disorders)
Duration	≥6 mo	

Symptoms	Conflict between experienced and assigned gender:	**Transsexualism:** desire to live as member of the opposite sex
	Children	**Dual-role transvestism:** temporarily wearing clothes of opposite sex to experience the other gender, but not desiring sex change.
	• Desire or insistence of being another gender	
	• Dressing like the other gender	**Gender identity disorder of childhood:**

and is living as the other gender

Other Specified

The category *other specified gender dysphoria* is for cases where the presentation causes clinically significant distress or impairment but does not meet the full criteria for gender dysphoria. When using this diagnosis, the clinician should specify why the full criteria were not met.

Unspecified

The category *unspecified gender dysphoria* can be applied when full criteria are not met, and the clinician chooses not to specify the reason.

A 27-year-old assigned female at birth was referred to a gender identity clinic reporting having felt different as a child from other girls, although unable then to identify the source. As a young girl, she enjoyed playing sports with girls and boys but generally preferred the companionship of boys. She preferred wearing unisex or boyish clothes and resisted wearing a skirt or dress. Everyone referred to her as a tomboy. She tried to hide her breast development by wearing loose-fitting tops and stooping forward. Menses were embarrassing and poignantly reminded her of her femaleness, which was becoming increasingly alienating. As sexual attractions evolved, they were directed exclusively to female partners. In her late teens, she had one sexual experience with a man, and it was aversive. She began socializing in lesbian circles, but did not feel comfortable there and did not consider herself lesbian, but more a man. For sexual partners, she wanted heterosexual women and wanted to be considered by the partner as a man. As gender dysphoric feelings became increasingly pronounced, she consulted transsexual sites on the Internet and contacted a female-to-male transsexual community support group. She then set into motion the process of clinical referral. She transitioned to living as a man, had a name change, and received androgen injections. The patient's voice deepened, facial and body hair grew, menses stopped, and sex drive increased, along with clitoral hypertrophy. After 2 years,

the patient underwent a bilateral mastectomy and was on the waitlist for phalloplasty and hysterectomy–oophorectomy. Employment as a man continues, as does a 3-year relationship with a female partner. The partner has a child from a previous marriage. (Adapted from a case of Richard Green, M.D.)

DIFFERENTIAL DIAGNOSIS

Differential Diagnosis of Children

Children diagnosed with gender dysphoria predicted to be more likely than others to identify as transgender as adults are differentiated from other gender-nonconforming children by statements about desired anatomical changes, as well as the persistence of the diagnosis over time. Children whose gender dysphoria persists over time may make repeated statements about a desire to be or believe that they are another gender. Other gender-nonconforming children may make these statements for short periods but not repeatedly, or may not make these types of statements, and may instead prefer clothing and behaviors associated with another gender but show contentment with their birth-assigned gender.

The diagnosis of gender dysphoria no longer excludes intersex people and instead is coded with a specifier in the cases where intersex people are gender dysphoric about their birth-assigned gender. Medical history is important to distinguish between children with or without intersex conditions. The standards of care for intersex children have changed dramatically over the last few decades due to activism by intersex adults and supportive medical and mental health professionals. Historically, intersex babies were often subjected to early surgical procedures to create a more standard male or female appearance. These procedures had the potential to cause sexual dysfunction, such as inability to orgasm, and permanent sterility. Recently, these practices have changed considerably so that more intersex people can make decisions about their bodies later in life.

Differential Diagnosis of Adolescents and Adults

Those who meet the criteria for a diagnosis of gender dysphoria must

experience clinical distress or impairment related to their gender identity. This requirement excludes the diagnosis of transgender or gender-nonconforming people who are not clinically distressed by their gender identities. There are certain mental illnesses in which transgender identity may be a component of delusional thinking, such as in schizophrenia. However, this is extremely rare and is different from transgender identity or gender dysphoria as the gender identity issues diminish with the treatment of the psychosis. Body dysmorphic disorder may be a differential diagnosis for some patients who present with a desire to change gendered body parts. However, with body dysmorphic disorder, the focus is on the body part looking abnormal, not on gender. Transvestic disorder, discussed in the previous chapter, is a recurrent and intense sexual arousal from cross-dressing that causes clinically significant distress or impairment. This diagnosis is differentiated from gender dysphoria by the patient's gender identity being consistent with their gender assigned at birth, and by sexual excitement linked to cross-dressing coming to interfere with the person's life.

COURSE AND PROGNOSIS

Children

Children typically begin to develop a sense of their gender identity around age 3. At this point, they may develop gendered behaviors and interests, and some may begin to express a desire to be another gender. It is often around school age that children are first brought for clinical consultations, as this is when they begin to interact with classmates closely and to be scrutinized by adults other than their caregivers. Some adults who identify as transgender recall that as children, they did not show behaviors consistent with another gender then. Some say later that they worked hard to appear stereotypical to their assigned gender, whereas others deny being able to recall gender identity concerns. Approaching puberty, many children diagnosed with gender dysphoria begin to show increased levels of anxiety related to anticipated changes to their bodies.

Children diagnosed with gender dysphoria do not necessarily grow up to identify as transgender adults. Several studies have demonstrated that more than half of those diagnosed with gender identity disorder, based on the

DSM-IV, later identify with their birth-assigned gender once they reach adulthood. Those children who do identify as transgender as adults tend to have more extreme gender dysphoria as children. Many studies show increased rates of gay and bisexual identity among those who were gender nonconforming as children.

COMORBIDITY

Comorbidity in Children

Children diagnosed with gender dysphoria show higher rates than other children of depressive disorders, anxiety disorders, and impulse control disorders. This high rate is likely related to the stigma faced by these children related to their gendered behaviors and identities. There are also reports that those diagnosed with gender dysphoria are more likely than others to fall on the autism spectrum. Some researchers posit that this may be related to intrauterine hormone exposure.

Comorbidity in Adults

Adults diagnosed with gender dysphoria show higher rates than other adults of depressive disorders, anxiety disorders, suicidality, self-harming behaviors, and substance abuse. The lifetime rate of suicidal thoughts in transgender people is about 40 percent. The minority stress model predicts increases in mental illness in groups that are stigmatized, discriminated against, harassed, and abused at higher rates than others. DSM-5 reports that persons with late-onset gender dysphoria may have more significant fluctuations in the extent of their distress and more ambivalence about and less satisfaction after sex reassignment surgery.

TREATMENT

Children

Treatment of gender identity issues in children typically consists of individual, family, and group therapy that guides children in exploring their gendered interests and identities. Some providers practice reparative, or conversion therapy, which attempts to change a person's gender identity or

sexual orientation. This type of therapy is contrary to position statements by the American Psychiatric Association and practice guidelines of the American Academy of Child and Adolescent Psychiatry, and we consider this to treatment to be unethical.

Adolescents

As gender-nonconforming children approach puberty, some show intense fear and preoccupation related to the physical changes they anticipate or are beginning to experience. In addition to providing psychotherapy, many clinicians use these adolescents' reactions to the first signs of puberty as a compass to determine if puberty-blocking medications should be a consideration. Puberty-blocking medications are gonadotropin-releasing hormone (GnRH) agonists that can temporarily block the release of hormones that lead to secondary sex characteristics, giving adolescents and their families time to reflect on the best options moving forward. GnRH agonists are used in other populations (e.g., children with precocious puberty) and thought safe. However, we should consider such steps carefully.

Adults

Treatment of adults who identify as transgender may include psychotherapy to explore gender issues, hormonal treatment, and surgical treatment. Hormonal and surgical interventions may decrease depression and improve the quality of life for such persons.

Mental Health Treatment

The history of poor treatment and medicalization of transgender people by mental health providers has led to a decreased interest on the part of trans-identified people in engaging in mental health care. Many surgeons, and some physicians who prescribe transition-related hormones, require a letter from a mental health provider, so for many transgender people, the mental health worker is a gatekeeper. Many community clinics are now using informed consent models for hormone treatment, thereby decreasing the need for mental health providers to play the role of gatekeepers. The World Professional Association for Transgender Health (WPATH) Standards of Care (SOC) for the health of transsexual, transgender, and gender-

nonconforming people have recently become more flexible and open to informed consent models. Some mental health providers are specializing in working with transgender populations, and this is increasing the rate at which transgender people engage in psychotherapy.

Hormones

Hormone treatment of transgender men most often involves testosterone, usually taken by injection every week or every other week. Initial changes with testosterone therapy include increased acne, muscle mass, and libido, as well as a cessation of menses, usually within the first few months. Subsequent and more permanent changes include deepening of the voice, increased body hair, and enlargement of the clitoris. Monitoring includes hemoglobin/hematocrit levels, as testosterone can rarely cause an increase in red blood cell counts that can lead to stroke. Like all steroid hormones, the liver metabolizes testosterone, so we should obtain routine liver function tests. Clinicians also want to monitor cholesterol and screen for diabetes, as testosterone treatment may increase the likelihood of lipid abnormalities and diabetes. Those beginning hormone treatments are routinely counseled on fertility, as future fertility may be affected by testosterone.

Transgender women may take estrogen, testosterone-blockers, or progesterone, often in combination. These hormones can cause softening of the skin and redistribution of fat, as well as breast growth. Breast development varies between people but does not generally exceed bra cup size B. Experts recommend for patients to be on hormones for 18 to 24 months before having breast augmentation, allowing the breasts to develop to their final size. Sex drive can decrease, as well as erections and ejaculation. Body hair can decrease somewhat, but often not as much as desired, prompting many women to obtain electrolysis. There is no change in voice, as testosterone has permanently altered the vocal cords, and many women seek out voice coaching. Those on estrogen should avoid cigarette smoking, as the combination can lead to an increased risk of blood clots. We should monitor blood pressure, as well as liver function and cholesterol. Also, providers routinely test prolactin as this hormone can increase with estrogen therapy, and in rare cases, transgender women may develop prolactinomas. Reproductive counseling is essential before beginning estrogen treatment

because permanent sterility is almost always the outcome.

Surgery

Many fewer people undergo gender-related surgeries than take hormones. Some people do not desire gender-related surgeries. Others cannot afford them or are not convinced that they will be satisfied with the currently available results.

The most common type of surgery for both trans men and trans women is "top surgery," or chest surgery. Transgender men may have surgery to construct a male-contoured chest. Trans-women may have breast augmentation.

"Bottom surgery" is less common. Transgender men may have a metoidioplasty, in which the surgeon frees the clitoris from the ligament, attaching it to the body, and adds tissue increasing its length and girth. Scrotoplasty, the placement of testicular implants, is another way to create male-appearing genitalia. Phalloplasty, the creation of a penis, is less commonly performed because it is expensive, involves multiple procedures, requires donor skin from another part of the body, and has limited functionality. Bottom surgery for women is typically vaginoplasty, also commonly known as Sex Reassignment Surgery (SRS). Here, the surgeon removes the testicles, reconstructs the penis to form a clitoris, and creates a vagina. Techniques for vaginoplasty are becoming very good, but the procedure remains expensive. Because of this, some women, especially those with less money, may have orchiectomies, where the surgeon removes the testicles. These can be in-office procedures with a local anesthetic. The procedure is useful for substantially decreasing the body's production of androgens like testosterone. Less widely discussed, but essential to many women, are facial feminization surgeries that alter the cheeks, forehead, nose, and lips to create a more feminine facial appearance. The face is often used by persons to recognize gender in another person, and having facial features that match the affirmed gender can facilitate social interaction and provide safety from harassment and violence. Transgender men rarely undergo facial surgeries, as testosterone typically causes the face to appear more masculine.

Because surgery is inaccessible to many, there are rare cases of self-surgery, and some people have surgeries performed under unsafe conditions.

Women may inject industrial-grade silicone to produce body curves. Silicone injection done without the supervision of a medical professional can result in body mutilation, infection, and even silicone blood clots that can lead to embolism and death.

EPIDEMIOLOGY

Children

Most children with gender dysphoria come to clinical attention in early grade school years. Parents, however, typically report that the cross-gender behaviors were apparent before 3 years of age. Among a sample of boys younger than age 12 referred for a range of clinical problems, the reported desire to be the other sex was 10 percent. For clinically referred girls younger than age 12, the reported desire to be the other sex was 5 percent. The sex ratio of children referred for gender dysphoria is 4 to 5 boys for each girl, which is likely due in part to societal stigma directed toward feminine boys. The sex ratio is equal in adolescents referred for gender dysphoria. Researchers have observed that many children considered to have shown gender-nonconforming behavior do not grow up to be transgender adults; conversely, many people who later come out as transgender adults report that they were not identified as gender nonconforming during childhood.

Adults

The estimates of gender dysphoria in adults emanate from European hormonal/surgical clinics with a prevalence of 1 in 11,000 male- and 1 in 30,000 female-assigned people. DSM-5 reports a prevalence rate ranging from 0.005 to 0.014 percent for male- and 0.002 to 0.003 percent for female-assigned people. Most clinical centers report a sex ratio of three to five male patients for each female patient. Most adults with gender dysphoria report having felt different from other children of their same sex, although, in retrospect, many could not identify the source of that difference. Many report feeling extensively cross-gender identified from the earliest years, with the cross-gender identification becoming more profound in adolescence and young adulthood. Overall the prevalence of male to female dysphoria is higher than female to male dysphoria. An important factor in diagnosis is that

there is greater social acceptance of birth-assigned females dressing and behaving as boys (so-called tomboys) than there is of birth-assigned males acting as females (so-called sissies). Some researchers speculate that 1 in 500 adults may fall somewhere on a transgender spectrum, based on population data rather than clinical data.

ETIOLOGY

Biologic Factors

For mammals, the resting state of tissue is initially female. Males only develop if the body introduces androgen, which is set off by the Y chromosome. The result is testicular development. Without testes and androgen, female external genitalia develop. Thus, maleness and masculinity depend on fetal and perinatal androgens. Sex steroids govern sexual behavior in lower animals, but this effect diminishes as the evolutionary tree is scaled. Sex steroids influence the expression of sexual behavior in mature men or women; that is, testosterone can increase libido and aggressiveness in women, and estrogen can decrease libido and aggressiveness in men. However, masculinity, femininity, and gender identity are more a product of postnatal life events than the prenatal hormonal organization.

Brain organization theory refers to the masculinization or feminization of the brain in utero. Testosterone affects brain neurons that contribute to the masculinization of the brain in such areas as the hypothalamus. Whether testosterone contributes to so-called masculine or feminine behavioral patterns remains a controversial issue.

Genetic causes of gender dysphoria are under study, but we have not identified candidate genes, and chromosomal variations are uncommon in transgender populations. Case reports of identical twins have shown some pairs that are concordant for transgender issues and others that are not.

A variety of other approaches to understanding gender dysphoria are underway. These include imaging studies that have shown changes in white matter tracts, cerebral blood flow, and cerebral activation patterns in patients with gender dysphoria, but this is preliminary work. An incidental finding is that transgender persons are likely to be left-handed, the significance of which is unknown.

Psychosocial Factors

Children usually develop a gender identity consonant with their assigned sex. Many factors influence the formation of gender identity, including children's temperament and the interaction of that with parents' qualities and attitudes. Culturally acceptable gender roles exist: Society does not expect boys to be effeminate, or girls to be masculine. There are boys' games (e.g., cops and robbers) and girls' toys (e.g., dolls and dollhouses). Children learn these roles, although some investigators believe that some boys are temperamentally delicate and sensitive and that some girls are aggressive and energized—traits that are stereotypically known in today's culture as feminine and masculine, respectively. However, in Western society, we have a higher tolerance for "nontraditional" gender role behaviors than we once did.

Sigmund Freud believed that gender identity problems resulted from conflicts experienced by children within the oedipal triangle. In his view, both real family events and children's fantasies fuel these conflicts. Whatever interferes with a child loving the opposite-sex parent and identifying with the same-sex parent interferes with healthy gender identity development.

Since Freud, psychoanalysts have postulated that the quality of the mother–child relationship in the first years of life is paramount in establishing gender identity. During this period, mothers usually facilitate their children's awareness of, and pride in, their gender: they value their children as little boys and girls. Analysts argue that devaluing, hostile mothering can result in gender problems. At the same time, the separation–individuation process is unfolding. When gender problems become associated with separation–individuation problems, the result can be the use of sexuality to remain in relationships characterized by shifts between a desperate infantile closeness and a hostile, devaluing distance.

Some children receive the message that they would be more valued if they adopted the gender identity of the opposite sex. Rejected or abused children may act on such a belief. A mother's death, extended absence, or depression can influence the process, and a young boy may react by totally identifying with her—that is, by becoming a mother to replace her.

The father's role is also vital in the early years, and his presence can help the separation–individuation process. Without a father, the mother and child

may remain overly close. For a girl, the father usually is the prototype of future love objects; for a boy, the father is a model for male identification.

Learning theory postulates that children may be rewarded or punished by parents and teachers based on gendered behavior, thus influencing the way children express their gender identities. Children also learn how to label people according to gender. Eventually, they also learn that we should not dictate gender based on surface appearances such as clothing or hairstyle.

18

Disruptive, Impulse-Control, and Conduct Disorders

Six conditions comprise the category of *disruptive, impulse-control, and conduct disorders.* They include two that are associated with childhood: (1) oppositional defiant disorder and (2) conduct disorder; we discuss both in Chapter 2. DSM-5 includes antisocial personality disorder in both this section and in the personality disorders section; we will consider that with the personality disorders (Chapter 19). The remaining three disorders are intermittent explosive disorder, kleptomania, and pyromania, which are discussed here as well as other specified and unspecified disorders that relate to this category.

THE CLINICAL PRESENTATION

Persons suffering from one of these disorders have either an inability to resist an intense impulse or drive or are tempted to perform a particular act that is clearly harmful to themselves or others, or both. Before the event, the individual usually experiences mounting tension and arousal, sometimes— but not consistently—mingled with conscious anticipatory pleasure. Completing the action brings immediate gratification and relief. Within a variable time afterward, the individual experiences a conflation of remorse, guilt, self-reproach, and dread. Shameful secretiveness about the repeated impulsive activity frequently expands to permeate the individual's entire life, often delaying treatment.

Intermittent Explosive Disorder

Patients with intermittent explosive disorder have discrete episodes of losing control of their aggressive impulses; these episodes can result in severe assault or the destruction of property. The aggressiveness expressed is grossly out of proportion to any stressors that may have helped elicit the events. The episodes appear within minutes or hours and, regardless of duration, remit spontaneously and quickly. After each episode, patients usually show genuine regret or guilt, and signs of generalized impulsivity or aggressiveness are absent between events. Clinicians should not diagnose intermittent explosive disorder if they can better explain the symptoms with another disorder: one can imagine a long list of possible disorders, and we discuss some differentials in that section.

A 36-year-old real estate agent sought assistance for difficulty with his anger. He was quite competent at his job, although he frequently lost clients when he became enraged over their indecisiveness. On several occasions, he became verbally abusive, leading clients to find ways out of escrow closings. The impulsive aggression also led to the termination of multiple relationships because sudden angry outbursts contained demeaning accusations toward his girlfriends. These outbursts frequently occurred in the absence of any apparent conflict. On numerous occasions, the patient became so uncontrollably enraged that he threw things across the room, including books, his desk, and the contents of the refrigerator. Between episodes, he was a kind and likable individual with many friends. He enjoyed drinking on the weekends and had a history of two arrests for driving while intoxicated. On one of these occasions, he became involved in a verbal altercation with a police officer. He had a history of drug experimentation in college that included cocaine and marijuana.

A mental status examination revealed a generally cooperative patient. However, he became quite defensive when questioned about his anger and quickly felt accused and blamed by the interviewer for his past behaviors. He had no significant medical history and no signs of neurologic problems. He had never been in psychiatric treatment before this evaluation. He was on no medications. He denied any symptoms of a mood disorder or any other antisocial activity.

Treatment included the use of carbamazepine and a combination of supportive and cognitive-behavioral psychotherapy. The patient's angry outbursts improved as he became aware of the early signs that he was about to lose control. He learned techniques to avoid confrontation when such warning signs occurred. (Courtesy of Vivien K. Burt, M.D., Ph.D. and Jeffrey William Katzman, M.D.)

Kleptomania

Patients with kleptomania (from the Greek *kleptēs,* "thief") describe a recurrent failure to resist the impulse to steal objects, even though they have no need for the objects—often it has no value to the person, monetary or otherwise, and the patient could have easily afforded it. For patients with this disorder, the goal is not to obtain a specific item, it is the act of stealing itself. After taking the objects, the patient often gives them away, returns them secretly, or hides them.

As with other impulse-control disorders, patients with kleptomania experience mounting tension before the act, followed by gratification and lessening of tension after the action. They may or may not feel guilt or remorse and might feel depressed about their behavior. The theft is not planned and does not involve others. Although patients are unlikely to take something when immediate arrest is probable (e.g., in front of a security guard at a store), they may not rationally consider the risks involved even though repeated arrests lead to pain and humiliation. Patients may feel guilt and anxiety after the theft, but they do not feel anger or vengeance.

Jane was a 42-year-old, highly successful, single executive from a wealthy background. She called herself a "shop-'til-you-drop type" and had always been able to afford the expensive designer clothing that she loved. Since college, her "legit" shopping had been paralleled by "boosting" cheap panties and brassieres from discount stores. She did not wear the stolen items; indeed, she considered them "sleazy." She could never bring herself to get rid of them either and kept boxes filled with stolen lingerie in a storage facility.

Jane talked or bought her way out of trouble until her 30s when she

was arrested while stealing pantyhose from the same K-Mart for the third time in as many months. As a condition of probation, she was ordered to see a psychiatrist. Her attendance was sporadic, and several more thefts occurred over the next 2 years. She also experienced substantial depression, which she tried to alleviate by heavy drinking.

Jane finally began taking her problem seriously after yet another arrest precipitated a suicidal gesture. She started keeping appointments regularly and consented to take citalopram and naltrexone. She believes that her participation in an Alcoholics Anonymous (AA) group for high-pressured executives has been at least as effective—if not more so—in controlling her stealing. (Courtesy of Harvey Roy Greenberg, M.D.)

Table 18-1
Intermittent Explosive Disorder

	Intermittent Explosive Disorder	
Disorder	**DSM-5**	**ICD-10**
Diagnostic name	Intermittent explosive disorder	Other habit and impulse disorders (intermittent explosive disorder)
Duration	If symptom 1, average of 2×/wk for 3 mo If symptom 2, occurs for at least 1 y	
Symptoms	Nonpremeditated, unmotivated verbal or physical aggression, out of proportion to the provocation 1. Not causing damage 2. Causing damage	Persistently repeated maladaptive behavior Failure to resist the impulse Preceded by a period of tension Followed by a period

		of release
Required number of symptoms	Either 1 or 2 above If symptom 2, has to occur at least 3 times within the year	All of above
Psychosocial consequences of symptoms	Distress or impaired functioning (social, occupational, or other significant areas) Or, financial or legal consequences	
Exclusions (not result of):	Medical illness Substance Other psychiatric disorder Age <6	Not secondary to another psychiatric syndrome
Comments		This is diagnosed as a habit and impulse disorder, "other," and not specifically defined

Diagnostic name	Kleptomania	Kleptomania
Symptoms	Recurrent stealing • Failure to resist the impulse to steal • Items stolen are not	Persistently repeated maladaptive behavior • Failure to resist the impulse

	needed • Preceded by a period of tension • Followed by a period of gratification or release	• Preceded by a period of tension • Followed by a period of release
Required number of symptoms	All of above	All of above
Exclusions (not result of):	Anger Vengeance Psychosis Conduct disorder Mania Antisocial personality disorder	Not secondary to another psychiatric syndrome
Comments		Included among the habit and impulse disorders

Pyromania

Patients with pyromania repeatedly and deliberately set fires. They feel an urge to do this and relief or pleasure after they do. They typically are fascinated with all aspects of fires and may set off false alarms. They often are attracted to firefighting, may spend time at their local fire department, volunteer, or even become professional firefighters. Their curiosity is evident, but they show no remorse and may be indifferent to the consequences for life or property. Firesetters may gain satisfaction from the resulting destruction; frequently, they leave apparent clues.

DIAGNOSIS

Intermittent Explosive Disorder

Table 18-1 lists the diagnostic approaches to intermittent explosive disorder in DSM-5 and ICD-10. The key feature of this disorder is an aggressive outburst that has a rapid onset, typically without warning, lasting for less than 30 minutes. There is usually some provocation, although the response is disproportionate to that provocation. A less severe episode may occur in between the more severe ones.

As with most psychiatric disorders, the disorders cause significant distress or impairment in psychosocial functioning and are not better accounted for by another psychiatric, substance use, or other medical disorder. Relatively unique to this disorder is an age requirement, in which the individual has to be above the age of 6 years (or of comparable developmental level).

The diagnosis of intermittent explosive disorder should be the result of history-taking that reveals several episodes of loss of control associated with aggressive outbursts. One discrete episode does not justify the diagnosis. The histories typically describe a childhood in an atmosphere of an alcohol use disorder, violence, and emotional instability. Patients' work histories are poor; they report job losses, marital difficulties, and trouble with the law. Most patients have sought psychiatric help in the past but to no avail. Anxiety, guilt, and depression usually follow an outburst, but this is not a constant finding.

Kleptomania

Table 18-2 lists the diagnostic approaches to kleptomania in DSM-5 and ICD-10. The essential feature of kleptomania is recurrent, intrusive, and irresistible urges or impulses to steal unneeded objects. The act is accompanied by tension before the action and pleasure, gratification, or relief after it. It is not associated with anger or vengeance and is not better explained by some other disorder, as discussed in the Differential section.

Pyromania

Table 18-3 lists the diagnostic approaches to kleptomania in DSM-5 and ICD-10. To be diagnosed with pyromania, patients must set fires, not just desire or imagine them. This action is repetitive, deliberate, and purposeful. They feel tension or arousal before setting the fires as well as a fascination

and attraction to fires. They may make considerable preparations before starting the fire. After setting the fire, they feel pleasure, gratification or relief when witnessing or participating in the aftermath of the fire. Perhaps related to that gratification, they also feel a similar attraction and interest with firefighting, including the activities and equipment associated with that profession. Like the discussion of kleptomania, they do not personally benefit, financially or otherwise, from the fire, hence the distinction between pyromania and arson, and the disorder is not better explained by another cause (see the Differential section).

Other Specified or Unspecified Disorders

DSM includes "other specified or unspecified disorders" for most of the diagnostic categories. This is usually a residual category for disorders that do not meet the criteria for the major disorders in the class. In this case, this group includes some unique disorders, some of which stand at the border between impulsive and compulsive disorders (see the section on Differential Diagnosis for a discussion of the difference). Many of these, such as Internet gaming disorder and related, are better considered as addictive disorders and included in our substance use disorders chapter. This is because even though not due to substances, the phenomenology, pathology, course, and treatment approach of disorders such as Internet gaming disorder appears to be very similar.

OBJECTIVE TESTS FOR THE DISORDERS

Physical Findings and Laboratory Examination

Blood chemistry (liver and thyroid function tests, fasting blood glucose, electrolytes), urinalysis (including drug toxicology), and syphilis serology may help rule out other causes of aggression or impulsive behavior. Magnetic resonance imaging (MRI) may reveal changes in the prefrontal cortex, which is associated with loss of impulse control.

DIFFERENTIAL DIAGNOSIS FOR THE DISRUPTIVE AND IMPULSE-CONTROL DISORDERS

It can be challenging to distinguish between impulse disorders and compulsive disorders, and the terms in practice are sometimes vague and overlapping. Technically, an *impulse* is a tension state that can exist without an action; a *compulsion* is a tension state that always has an action component. In the case of compulsive disorders (such as obsessive-compulsive disorder [OCD] or trichotillomania), the patients feel "compelled" to act out their pathologic behavior; they cannot resist the impulse to do so. Impulses and compulsions also differ by their expected result: people acting on an impulse expect to receive some pleasure, whereas compulsions are often ego-dystonic, meaning that a person does not desire or enjoy the act despite feeling compelled to do it. Even this is complicated, as in some cases impulse-control disorders also elicit guilt, which disturbs the sense of pleasure. Similarly, not all compulsions are ego-dystonic; for example, compulsive video game playing may have a pleasurable component. Both impulsive and compulsive behaviors are repetitive; however, the repeated acting out of impulses leads to psychosocial impairment, whereas compulsive behavior does not always carry that risk.

Intermittent Explosive Disorder

One should only diagnose an intermittent explosive disorder after other disorders associated with the occasional loss of control of aggressive impulses have been ruled out as the primary cause. These other disorders include psychotic disorders, personality change because of a general medical condition, antisocial or borderline personality disorder, substance intoxication (e.g., alcohol, barbiturates, hallucinogens, amphetamines), epilepsy, brain tumors, degenerative diseases, and endocrine disorders.

**Table 18-3
Pyromania**

	Pyromania	
Disorder	**DSM-5**	**ICD-10**
Diagnostic name	Pyromania	Pyromania

Symptoms	Fire setting • 1+ incidents • Deliberate and purposeful • Preoccupied by fire, burning, and related phenomena • Followed by a period of gratification or release	Fire setting • Multiple acts or attempts • No apparent motive • Preoccupied by fire, burning, and related phenomena • Preceded by a period of tension • Followed by a period of excitement
Required number of symptoms	All of above	All of above
Exclusions (not result of):	• Conduct disorder • Mania • Antisocial personality disorder • Psychosis • Impaired cognition or judgment Motivated by: • Desire for a perceived financial or social benefit • Sociopolitical ideology • Need to conceal criminal activity • Anger • Vengeance	• Dissocial personality disorder • Alcohol or substance disorder • Feigned illness • Conduct disorder • Organic mental disorder • Schizophrenia
Comments		Included among the habit and impulse disorders

The episodic and discrete nature of intermittent explosive disorder differentiates it from conduct disorder and antisocial personality disorder, which are more pervasive patterns of behavior in which aggression is a consistent feature, and not just associated with discrete outbursts.

In schizophrenia, patients may display violent behavior in response to delusions and hallucinations, and they show gross impairments in reality testing. Hostile patients with mania may be impulsively aggressive, but the underlying diagnosis is generally apparent from their mental status examinations and clinical presentations.

Amok is a culture-bound syndrome usually associated with southeastern Asia (but also seen elsewhere), which consists of episodes of acute violent behavior for which the person claims amnesia. It is distinguished from intermittent explosive disorder by a single episode and prominent dissociative features.

Among medical disorders, certain neurologic disorders can resemble impulse-control disorders. The best-documented examples are with Parkinson disease, which can resemble both impulse-control disorders and addictive disorder.

Kleptomania

Shoplifting has become a national epidemic. Few shoplifters have true kleptomania; most are teenagers and young adults who steal in pairs or small groups for "kicks" as well as goods and do not have a psychiatric disorder.

Individuals with an antisocial personality disorder steal for personal gain, with some degree of premeditation and planning. Often they convince others to rob for them. Antisocial stealing regularly involves the threat of harm or actual violence, mainly to elude capture. Guilt and remorse are distinctively lacking, or patients are patently insincere.

Episodes of theft occasionally occur during psychotic illness, for example, acute mania, major depression with psychotic features, or schizophrenia. Psychotic stealing is a product of pathologic elevation or depression of mood or command hallucinations or delusions.

Acute intoxication with drugs or alcohol may precipitate theft in an individual with another psychiatric disorder or without significant psychopathology. Patients with Alzheimer disease or other dementing

organic illness may leave a store without paying, owing to forgetfulness rather than larcenous intent.

Some individuals with an antisocial personality disorder or no disorder may steal and then claim to suffer from kleptomania. This would be an example of malingering, not kleptomania, although with sufficiently intelligent perpetrators it may be challenging to tell the difference.

Pyromania

Clinicians should have little trouble distinguishing between pyromania and the fascination of many young children with matches, lighters, and fire as part of the normal investigation of their environments. One should also separate pyromania from incendiary acts of sabotage carried out by dissident political extremists or by arsonists.

When a fire setting occurs in conduct disorder and antisocial personality disorder, it is a deliberate act, not a failure to resist an impulse. Such individuals may set fires for profit, sabotage, or retaliation. Patients with schizophrenia or mania may set fires in response to delusions or hallucinations. Patients with brain dysfunction (e.g., dementia), mental retardation, or substance intoxication may set fires because of a failure to appreciate the consequences of the act.

COMORBIDITY

Intermittent Explosive Disorder

More than 80 percent of individuals with intermittent explosive disorder meet the criteria for another psychiatric disorder. These include other disorders of impulse-control and substance use, and mood, anxiety, personality (antisocial and borderline), posttraumatic stress, and eating disorders. Also, individuals with intermittent explosive disorder have been reported to be at increased risk of self-harm.

Kleptomania

Patients with kleptomania are said to have high lifetime comorbidity of major mood disorders (usually, but not exclusively, depressive) and various anxiety disorders. Associated conditions also include other disorders such as

pathologic gambling and compulsive shopping, eating disorders (especially bulimia nervosa), personality disorders, OCD, and substance use disorders, especially alcohol use disorder. Individuals with kleptomania are also reported to have higher rates of suicide.

Pyromania

Pyromania is significantly associated with substance use disorders (especially alcohol and marijuana use disorders), affective disorders, depressive or bipolar, and other impulse-control disorders. They are also reported to have increased suicidal thoughts.

COURSE AND PROGNOSIS

Intermittent Explosive Disorder

Intermittent explosive disorder may begin at any stage of life but usually appears between late adolescence and early adulthood. The onset can be sudden or insidious, and the course can be episodic or chronic. In most cases, the disorder decreases in severity with the start of middle age, but heightened organic impairment can lead to frequent and severe episodes. Intermittent explosive disorder is more common in men than women.

Kleptomania

Kleptomania may begin in childhood, although most children and adolescents who steal do not become kleptomaniac adults. The onset of the disorder generally is adolescence. In quiescent cases, loss or disappointment may precipitate new bouts of the disorder.

The course of the disorder waxes and wanes but tends to be chronic—the frequency of stealing ranges from less than one to multiple episodes per month. Most patients with kleptomania steal from retail stores, but they may also take from family members in their households. People with the disorder sometimes have bouts of being unable to resist the impulse to steal, followed by free periods that last for weeks or months. The spontaneous recovery rate of kleptomania is unknown.

Severe impairment and complications are usually secondary to being caught, particularly to being arrested. Many persons seem never to have

consciously considered the possibility of facing the consequences of their acts. Often, the disorder in no way impairs a person's social or work functioning.

The prognosis with treatment can be good, but few patients come for help of their own accord.

Pyromania

It should not be too surprising that we know very little about the development and course of pyromania. Most individuals with pyromania start setting fires in adolescence or young adulthood. The frequency and intensity of fire setting may increase over time or may wax and wane. The course of pyromania is unknown, but smaller studies suggest it may be chronic. Pyromania occurs more frequently in males with weaker social skills and learning difficulties.

TREATMENT APPROACH

Intermittent Explosive Disorder

A combined pharmacologic and psychotherapeutic approach has the best chance of success. Psychotherapy with patients who have an intermittent explosive disorder is difficult, however, because of their angry outbursts. Therapists may have problems with countertransference and limit-setting. Group psychotherapy may be helpful, and family therapy is useful, especially when the explosive patient is an adolescent or a young adult. A goal of treatment is to have the patient recognize and verbalize the thoughts or feelings that precede the explosive outbursts instead of acting them out. Cognitive-behavioral therapy and contingency management may be helpful.

Anticonvulsants have long been used, with mixed results, in treating explosive patients. Lithium has been reported useful in generally lessening aggressive behavior, and carbamazepine, valproate, and phenytoin have been reported helpful. Some clinicians have also used other anticonvulsants (e.g., topiramate). Clinicians occasionally use benzodiazepines but the meds can cause disinhibition, thus worsening the behaviors.

Antipsychotics and tricyclic drugs have been effective in some cases, but clinicians must then question whether schizophrenia or a mood disorder is the

correct diagnosis. With a likelihood of subcortical seizure-like activity, medications that lower the seizure threshold can aggravate the situation. Selective serotonin reuptake inhibitors (SSRIs), trazodone, and buspirone are useful in reducing impulsivity and aggression. Propranolol and other β-adrenergic receptor antagonists and calcium channel inhibitors have also been effective in some cases.

Some neurosurgeons have performed operative treatments for intractable violence and aggression. No evidence indicates that such treatment is effective.

Kleptomania

Because true kleptomania is rare, reports of treatment tend to be individual case descriptions or a short series of cases. Insight-oriented psychotherapy and psychoanalysis have been successful but depend on patients' motivations. Those who feel guilt and shame may be helped by insight-oriented psychotherapy because of their increased motivation to change their behavior.

Case reports and case series suggest that cognitive-behavioral therapy may be helpful. Specific behavior therapies, including systematic desensitization, aversive conditioning, and a combination of aversive conditioning and altered social contingencies, have been reported successful, even when motivation was lacking. SSRIs, such as fluoxetine and fluvoxamine, appear to be effective in some patients with kleptomania; however, there are also reports of fluoxetine having no benefit in kleptomania. Case reports indicated successful treatment with tricyclic drugs, trazodone, lithium, valproate, topiramate, naltrexone, methylphenidate, and electroconvulsive therapy. In a controlled trial of antidepressants, escitalopram was found to have no benefit in treating kleptomania. Though limited by small sample size and open-label design, high-dose naltrexone was reported to be effective in reducing the urge to steal in patients with kleptomania.

Pyromania

Little has been written about the treatment of pyromania, and treating firesetters has been difficult because of their lack of motivation. No single treatment has been proved effective; as a result, most therapists try various

modalities, including behavioral approaches. Among the treatments attempted, CBT appears to be the most promising.

Because of the recurrent nature of pyromania, any treatment program should include the supervision of patients to prevent a repeated episode of fire setting. Incarceration may be the only method of avoiding a recurrence while their therapy can commence.

We should treat firesetting by children with the utmost seriousness. When possible we should consider intensive interventions, but as therapeutic and preventive measures, not as punishment. In the case of children and adolescents, treatment of pyromania or fire setting should include family therapy.

Several case reports have been published using SSRIs, lithium, naltrexone, stimulants, topiramate, valproate, carbamazepine, antiandrogen agents, clonazepam, and olanzapine. Unfortunately, many have reported no benefit from pharmacotherapy.

EPIDEMIOLOGY

For all these disorders, we do not know much about their epidemiology, as they are all underreported. This is understandable given the potential ramifications of self-reporting what is usually illegal behavior.

The lifetime prevalence rate for intermittent explosive disorder is estimated to be around 5 to 8 percent, and it appears to be more common in men than in women. The men are likely to be found in correctional institutions and the women in psychiatric facilities. In one study, about 2 percent of all persons admitted to a university hospital psychiatric service had an intermittent explosive disorder; 80 percent were men.

The prevalence of kleptomania is not known, but it is estimated to be about 0.6 percent. The range varies from 4 to 24 percent of those arrested for shoplifting. The male-to-female ratio is 1:3 in clinical samples.

No information is available on the prevalence of pyromania, but only a small percentage of adults who set fires have pyromania. The disorder is found far more often in men than in women. In the United States, 60 percent of individuals who set fires are adolescents; most, however, would not meet the criteria for pyromania.

ETIOLOGY

For all of these disorders, the cause is not known. Psychodynamic, psychosocial, and biologic factors all undoubtedly play an essential role. Some disruptive and impulse-control disorders may have common underlying neurobiologic mechanisms. Fatigue, constant stimulation, and psychic trauma can lower a person's resistance to control impulses.

Intermittent Explosive Disorder

Other factors associated with impulsive aggression include childhood exposure to violence, maltreatment, and neglect. One study found that there was significant association between intermittent explosive disorder and aversive childhood parenting environment comparable to other psychopathologies. Another study found that physical abuse in childhood was independently associated with intermittent explosive disorder, with impulsivity and aggression as the mediators of the relationship between physical abuse and intermittent explosive disorder. Others have shown that intermittent explosive disorder is associated with childhood exposure to interpersonal traumatic events.

Prefrontal cortical dysfunction has been associated with impulsive aggression. Some investigators suggest that disordered brain physiology, particularly in the limbic system, is involved in most cases of episodic violence. Compelling evidence indicates that serotonergic neurons mediate behavioral inhibition. Decreased serotonergic transmission, which can be induced by inhibiting serotonin synthesis or by antagonizing its effects, reduces the impact of punishment as a deterrent to behavior. The restoration of serotonin activity (e.g., by administering L-tryptophan, a serotonin precursor) restores the behavioral effect of punishment and may aid the control of violent tendencies. Low levels of CSF 5-hydroxyindoleacetic acid (5-HIAA) correlate with violent suicide attempts and impulsive aggression in some studies. High CSF testosterone concentrations are associated with aggressiveness and interpersonal violence in men. Antiandrogenic agents have been shown to decrease aggression.

Evidence indicates that intermittent explosive disorder is more common in first-degree biologic relatives of persons with the disorder than in the general population. This association does not imply a genetic etiology, as many other

familial and social factors are surely influential. A gene–environment interaction may exist where individuals who have specific serotonin gene polymorphisms may be more prone to impulsive aggression behavior after exposure to childhood maltreatment.

Kleptomania

We know little about the etiology of kleptomania. There have been case reports of kleptomania associated with head trauma, frontal lobe lesions, cortical atrophy, dementia, and hypoglycemia secondary to insulinoma. There are implications for subtle white matter pathology based on diffusion tensor imaging results. Another study found that although, as a group, patients with kleptomania did not show deficits on neuropsychological testing, the severity of illness was associated with impairment in executive functioning.

Data are lacking and limited regarding the genetics of kleptomania. A study found that individuals with kleptomania had more first-degree relatives with alcohol use disorders compared to controls. Serotonin and dopamine, as well as the opioid and glutamatergic neurotransmitter systems, may play a role in kleptomania. Additionally, there are higher rates of OCD in relatives of individuals with kleptomania compared to the general population.

Pyromania

The etiology of pyromania is also poorly understood. The literature on the origins of pyromania has suggested factors ranging from temperament to environmental factors and parental psychopathology. Other authors have suggested pyromania, and the other impulse-control disorders, may share a neurobiologic link with substance use disorders. Limited studies suggest that pyromania may be associated with lower concentration of norepinephrine and serotonin metabolites 3-methoxy-4-hydroxyphenylglycol (MHPG) and 5-hydroxyindoleacetic acid (5-HIAA).

Personality Disorders

The person-centered approach to understanding personality and its disorders distinguish psychiatry fundamentally from all other branches of medicine. A person is a self-aware human being, as C. Robert Cloninger said, not "a machine-like object that lacks self-awareness." Personality refers to all of the characteristics that distinguish a continually developing, self-organizing human being from a predictable machine-like object. In other words, personality refers to all the ways someone shapes and adapts in a unique way to an ever-changing internal and external environment.

Persons with personality disorders are far more likely to refuse psychiatric help and to deny their problems than persons with anxiety disorders, depressive disorders, or obsessive-compulsive disorder. In general, personality disorder symptoms are ego-syntonic (i.e., acceptable to the ego, as opposed to ego-dystonic) and alloplastic (i.e., adapt by trying to alter the external environment rather than themselves). Persons with personality disorders do not feel anxiety about their maladaptive behavior. Because they do not routinely acknowledge pain from what others perceive as their symptoms, they often seem disinterested in treatment and impervious to recovery.

THE CLINICAL PRESENTATION

Persons suffering from one of these disorders have long-standing, maladaptive behavior traits that are pervasive and apparent in a wide range of personal and social contexts.

Paranoid Personality Disorder

Persons with paranoid personality disorder have long-standing suspiciousness and mistrust of persons in general. They refuse responsibility for their feelings and assign responsibility to others. They are often hostile, irritable, and angry.

Schizoid Personality Disorder

Schizoid personality disorder is characterized by a lifelong pattern of social withdrawal. Others often see persons with schizoid personality disorder as eccentric, isolated, or lonely. Their discomfort with human interaction, their introversion, and their bland, constricted affect are noteworthy.

Schizotypal Personality Disorder

Persons with schizotypal personality disorder are strikingly odd or strange, even to laypersons. Magical thinking, peculiar notions, ideas of reference, illusions, and derealization are commonplace.

Antisocial Personality Disorder

Antisocial personality disorder is an inability to conform to the social norms that ordinarily govern many aspects of a person's adolescent and adult behavior. Although often characterized by continual antisocial or criminal acts, the disorder is not synonymous with criminality.

Borderline Personality Disorder

Patients with borderline personality disorder stand on the border between neurosis and psychosis, and they have extraordinarily unstable affect, mood, behavior, object relations, and self-image.

Histrionic Personality Disorder

Persons with histrionic personality disorder are excitable and emotional and behave in a colorful, dramatic, extroverted fashion. Accompanying their flamboyant aspects, however, is often an inability to maintain sincere, long-lasting attachments.

Narcissistic Personality Disorder

Individuals with narcissistic personality disorder have a heightened sense of self-importance, lack of empathy, and grandiose feelings of uniqueness. Underneath, however, their self-esteem is fragile and vulnerable to even minor criticism.

Avoidant Personality Disorder

Persons with avoidant personality disorder show extreme sensitivity to rejection and may lead socially withdrawn lives. Although shy, they are not asocial and show a great desire for companionship, but they need unusually strong guarantees of uncritical acceptance. We often describe this group as having an inferiority complex.

Dependent Personality Disorder

Patients with dependent personality disorder subordinate their own needs to those of others, get others to assume responsibility for significant areas of their lives, lack self-confidence, and may experience intense discomfort when alone for more than a brief period.

Obsessive-Compulsive Personality Disorder

Persons with obsessive-compulsive personality disorder typically are emotionally constricted, orderly, perseverative, stubborn, and indecisive. The essential feature of the disorder is a pervasive pattern of perfectionism and inflexibility.

Personality Change due to a General Medical Condition

Personality change due to a general medical condition is a significant occurrence. ICD-10 includes the category personality and behavioral disorders due to brain disease, damage, and dysfunction, which includes organic personality disorder, postencephalitic syndrome, and postconcussional syndrome. Persons with this disorder have a marked change in personality style and traits from their previous level of functioning. Patients must show evidence of a causative medical factor antedating the onset of personality change.

DIAGNOSIS

DSM-5's categorical approach to personality disorders is problematic. It seems counterintuitive to think that we can boil down disturbed personality into a few symptoms. Experts in the field have argued for a more dimensional approach that is grounded in research on temperament and personality, some of which we later describe. The DSM-5 Personality Disorders Workgroup did work on such a change, in which the clinician would focus on the impairments in a person's personality functioning, using an approach based on a widely accepted model of personality. Although the authors of DSM-5 did consider such a change, they felt it too radical a leap for clinical use. Instead, they included the approach that the workgroup recommended in a later section of the book, "Emerging Measures and Models." For now, the categorical approach remains. However, this remains a controversial area of psychiatry, and many rightly question the validity of this approach.

ICD-10, with its more descriptive approach, is a little less controversial. However, despite some wording differences, its approach is similar to DSM-5's, although it lists more disorders than does DSM-5.

Table 19-1 compares the general approaches to diagnosing personality disorders.

DSM-5 divides the disorders into three categories, or clusters: A, B, and C. Cluster A includes three personality disorders with odd, aloof features (paranoid, schizoid, and schizotypal). Cluster B includes four personality disorders with dramatic, impulsive, exploitative, and erratic features (borderline, antisocial, narcissistic, and histrionic). Cluster C includes three personality disorders sharing anxious and fearful features (avoidant, dependent, and obsessive-compulsive). Individuals frequently exhibit traits that are not limited to a single personality disorder. When a patient meets the criteria for more than one personality disorder, clinicians should diagnose each.

Many of the features of various personality disorders can occur during an episode of another mental disorder. We should only use a diagnosis of personality disorder when the features are typical of long-term functioning and are not limited to a discrete episode of another mental disorder. Likewise, when maladaptive behavior features are due to the direct psychological effects of another mental disorder, including substance use, a diagnosis of

personality disorder is not warranted. However, it is possible to diagnose personality change due to another medical condition such as temporal lobe epilepsy; in this case, we must specify the medical condition along with the associated diagnosis of personality change.

Table 19-1
Personality Disorders

Name	DSM-5 **General Personality Disorder**	ICD-10 **Disorders of Adult Personality and Behavior**
Duration	Persistent, long duration, usually since teens or early adulthood	Persistent
Symptoms	The symptoms comprise a fixed pattern of behavior. The domains include: • Cognitive and perceptual • Mood and affect • Interpersonal • Behavioral	Consistent, fixed, and inflexible pattern of behaviors, involving • Dysfunctional relationships • Distorted view of oneself

Table 19-2
Paranoid Personality Disorder: Specific Symptoms

DSM-5		ICD-10	
Paranoid Personality Disorder		**Paranoid Personality D**	
Suspiciousness, evident from the following (≥4): • Suspicion/persecutory thoughts • Doubting others' loyalty • Distrust, inability to confide in others • Interpreting experiences as threatening or hostile • Holds grudges • Feeling attacked by others • Distrusting partner's faithfulness	Exclusions (not result of): • *Schizophrenia* • *Depression with psychotic features* • *Other psychoses* • *Substance use* • *A medical condition*	• Excessive sensitivity to setbacks or insults • Suspiciousness • Interpreting experiences as threatening or hostile • Distrusting partner's faithfulness • May also be self-important or overall self-referential	Exc • • •

Cluster A: Odd and Eccentric

Paranoid Personality Disorder. The hallmarks of paranoid personality disorder are excessive suspiciousness and distrust of others expressed as a pervasive tendency to interpret the actions of others as deliberately demeaning, malevolent, threatening, exploiting, or deceiving. This tendency begins in early adulthood and appears in a variety of contexts. Almost invariably, those with the disorder expect to be exploited or harmed by others in some way. They frequently dispute, without any justification, friends' or associates' loyalty or trustworthiness. Such persons are often pathologically jealous and, for no reason, question the fidelity of their spouses or sexual partners. Persons with this disorder externalize their own emotions and use the defense of projection; they attribute to others the impulses and thoughts that they cannot accept in themselves. Ideas of reference and logically defended illusions are common. Table 19-2 compares the different approaches to diagnosing paranoid personality disorder.

On psychiatric examination, patients with paranoid personality disorder may be formal in their style and act baffled about having to seek psychiatric help. Muscular tension, an inability to relax, and a need to scan the environment for clues may be evident, and the patient's manner is often severe and humorless. Although some premises of their arguments may be false, their speech is goal-directed and logical. Their thought content shows evidence of projection, prejudice, and occasional ideas of reference.

Schizoid Personality Disorder. Persons with schizoid personality disorder seem to be cold and aloof; they display a remote reserve and show no involvement with everyday events and the concerns of others. They appear quiet, distant, seclusive, and unsociable. They may pursue their own lives with remarkably little need or longing for emotional ties, and they are the last to be aware of changes in popular fashion. Table 19-3 compares the different approaches to diagnosing schizoid personality disorder.

The life histories of such persons reflect solitary interests and success at noncompetitive, lonely jobs that others find difficult to tolerate. Their sexual lives may exist exclusively in fantasy, and they may postpone mature sexuality indefinitely. Persons with schizoid personality disorder usually reveal a lifelong inability to express anger directly. They often lack close friends or confidants and are indifferent to praise and criticism. Although persons with schizoid personality disorder appear self-absorbed and lost in

daydreams, they have an average capacity to recognize reality.

On an initial psychiatric examination, patients with schizoid personality disorder may appear ill at ease. They rarely tolerate eye contact, and interviewers may surmise that such patients are eager for the interview to end. Their affect may be constricted, aloof, or inappropriately severe, but underneath the aloofness, sensitive clinicians can recognize fear. These patients find it challenging to be lighthearted: their efforts at humor may seem adolescent and off the mark. Their speech is goal-directed, but they are likely to give short answers to questions and to avoid spontaneous conversation. They may occasionally use unusual figures of speech, such as an odd metaphor, and may be fascinated with inanimate objects or metaphysical constructs. Their sensorium is intact, their memory functions well, and their proverb interpretations are abstract.

(because of thoughts)	more like that for personality disorders

Schizotypal Personality Disorder. Schizotypal personality disorder is characterized by pervasive discomfort with and inability to maintain close relationships, as well as eccentric behavior. These individuals demonstrate peculiarities of thinking, behavior, and appearance. Taking a history may be difficult because of the patients' unusual way of communicating.

Patients with schizotypal personality disorder exhibit disturbed thinking and communicating. Although frank thought disorder is absent, their speech may be distinctive or peculiar, may have meaning only to them, and often needs interpretation. These patients may be superstitious or claim powers of clairvoyance and may believe that they have other special powers of thought and insight. Their inner world may contain vivid imaginary relationships and child-like fears and fantasies, and they may experience perceptual illusions, as well. Table 19-4 compares the different approaches to diagnosing schizotypal personality disorder.

Because persons with schizotypal personality disorder have poor interpersonal relationships and may act inappropriately, they are isolated and have few, if any, friends. Under stress, patients with schizotypal personality disorder may decompensate and have psychotic symptoms, but these are usually brief. Patients with severe cases of the disorder may exhibit anhedonia and severe depression.

Cluster B: Dramatic

Antisocial Personality Disorder. The hallmarks of antisocial personality disorder are pervasive disrespect for and infringement on the rights of others. A person has to be 18 years of age or older, has to have demonstrated this pattern of behavior since age 15, and must have demonstrated evidence of conduct disorder before the age of 15 years (conduct disorder involves a repetitive and persistent pattern of behavior in which they violate the fundamental rights of others or major age-appropriate social rules). Table 19-

compares the different approaches to diagnosing antisocial personality disorder.

Patients with antisocial personality disorder can often seem to be normal and even charming and ingratiating. Their histories, however, reveal many areas of disordered life functioning. Lying, truancy, running away from home, thefts, fights, substance abuse, and illegal activities are typical experiences that patients report as beginning in childhood. These patients often impress clinicians with the colorful, seductive aspects of their personalities, but the clinician may also regard them as manipulative and demanding. They frequently have a heightened sense of reality testing and often impress observers as having excellent verbal intelligence.

Table 19-5
Antisocial Personality Disorder: Specific Symptoms

DSM-5		ICD-10	
Antisocial Personality Disorder		**Dissocial Personality Disor**	
≥age 18 Began by age 15 Conduct disorder before age 15 (diagnosed or evidence for) (≥3): • Disregards legal and social rules/norms • Lies • Impulsive • Irritable or	Exclusions (not result of): • *Schizophrenia* • *Bipolar disorder*	• Disregards social norms • Unconcerned by others' feelings • Easily frustrated/distressed • Easily becomes aggressive • Blames others	Exclusic resul • Conc disc • Emo uns pers disc

> aggressive
> - Neglects
>   safety
>   (self/others)
> - Irresponsible
> - No remorse

Persons with antisocial personality disorder are highly representative of the so-called con men. They are incredibly manipulative and can frequently talk others into participating in schemes for easy ways to make money or to achieve fame or notoriety. These schemes may eventually lead the unwary to financial ruin, social embarrassment, or both. Those with this disorder do not tell the truth and cannot be trusted to carry out any task or adhere to any conventional standard of morality. Promiscuity, spousal abuse, child abuse, and drunk driving are frequent events in their lives. A notable finding is a lack of remorse for these actions; that is, they appear to lack a conscience.

Patients with antisocial personality disorder can fool even the most experienced clinicians. In an interview, patients can appear composed and credible, but beneath the veneer lurks tension, hostility, irritability, and rage. A stress interview, in which the clinician vigorously confronts the patient with inconsistencies in their histories, may be necessary to reveal the pathology. A diagnostic workup should include a thorough neurologic examination. Because patients often show abnormal EEG results and soft neurologic signs suggesting minimal brain damage in childhood, these findings may support the clinical impression.

Borderline Personality Disorder. Persons with borderline personality disorder almost always appear to be in a state of crisis. Mood swings are frequent. Patients can be argumentative at one moment, depressed the next, and later complain of having no feelings. Patients can have short-lived psychotic episodes rather than full-blown psychotic breaks, and the symptoms are circumscribed, fleeting, or questionable. The behavior of patients with borderline personality disorder is highly unpredictable, and their achievements are rarely at the level of their abilities. The painful nature of their lives reflects in their repetitive self-destructive acts. Such patients may

slash their wrists and perform other self-mutilation to elicit help from others, to express anger, or to numb themselves to overwhelming affect. Table 19-6 compares the different approaches to diagnosing borderline personality disorder.

Because they feel both dependent and hostile, persons with this disorder have tumultuous interpersonal relationships. They can be dependent on those with whom they are close and, when frustrated, can express enormous anger toward their intimate friends. Patients with borderline personality disorder cannot tolerate being alone, and they prefer a frantic search for companionship, no matter how unsatisfactory, to their own company. To assuage loneliness, if only for brief periods, they accept a stranger as a friend or behave promiscuously. They often complain about chronic feelings of emptiness and boredom and the lack of a consistent sense of identity (identity diffusion); when pressed, they may complain about how depressed they usually feel, despite the flurry of other affects.

Functionally, patients with borderline personality disorder distort their relationships by considering each person to be either all good or all bad. They see persons as either nurturing attachment figures or as hateful, sadistic figures who deprive them of security needs and threaten them with abandonment whenever they feel dependent. As a result of this splitting, the good person is idealized, and the bad person devalued. Shifts of allegiance from one person or group to another are frequent. Some clinicians use the concepts of panphobia, pananxiety, panambivalence, and chaotic sexuality to delineate these patients' characteristics.

Projective identification is a defense mechanism that often occurs in patients with borderline personality disorder. In this primitive defense mechanism, the patient projects intolerable aspects of themselves onto another person, inducing them to play the projected role, and the two persons act in unison. Therapists must be aware of this process so they can act neutrally toward such patients.

Histrionic Personality Disorder. Persons with histrionic personality disorder show a high degree of attention-seeking behavior. They tend to exaggerate their thoughts and feelings and make everything sound more vital than it is. They display temper tantrums, tears, and accusations when they are not the center of attention or are not receiving praise or approval. Table 19-7

compares the different approaches to diagnosing histrionic personality disorder.

Seductive behavior is typical in both sexes. Sexual fantasies about persons with whom patients are involved are common, but patients are inconsistent about verbalizing these fantasies and may be coy or flirtatious rather than sexually aggressive. Despite these behaviors, they may have a psychosexual dysfunction, such as anorgasmia. They may act on their sexual impulses to reassure themselves that they are attractive to the other sex. Their relationships tend to be superficial, however, and they can be vain, self-absorbed, and fickle. Their deep dependence needs make them overly trusting and gullible.

Table 19-6
Borderline Personality Disorder: Specific Symptoms

DSM-5	ICD-10	
Borderline Personality Disorder	**Emotionally Unstable Personality Disorder**	
Conflict/impulsivity (≥5): • Avoids abandonment • Intense, unstable relations marked by splitting • Unstable self-image • Self-harm, other impulsive behaviors • Suicidal ideation or behavior • Labile affect • Feeling empty inside • Poor anger management • Paranoia/dissociation, usually due to stress	• Impulsiveness • Labile mood • Outbursts • Interpersonal conflict Two subtypes: (1) Impulsive type (emotional lability and lack of impulse control) (2) Borderline type (poor self-image, self-worth, relationships, with associated self-harm)	Exclusions (not result of): • Dissocial personality disorder

Table 19-7
Histrionic Personality Disorder: Specific Symptoms

DSM-5	ICD-10
Histrionic Personality Disorder	**Histrionic Personality Disorder**
Needing attention, very emotional (≥5): • Uncomfortable when not the center of attention • Flirtatious, provocatively sexual • Emotionally labile • Physically provocative or flamboyant • Speech is vague • Speech is exaggerated/dramatic • Suggestible • Overestimates the intimacy of relationships	• Affect is shallow/labile • Self-dramatization • Speech and emotions are exaggerated • Suggestible • Egocentric • Not concerned with others • Attention seeking • Easily offended or hurt

The major defenses of patients with histrionic personality disorder are repression and dissociation. Accordingly, such patients are unaware of their true feelings and cannot explain their motivations. Under stress, reality testing quickly becomes impaired.

In interviews, patients with histrionic personality disorder are generally cooperative and eager to give a detailed history. Gestures and dramatic punctuation in their conversations are commonplace; they may make frequent slips of the tongue, and their language is colorful. Affective display is typical, but when pressed to acknowledge certain feelings (e.g., anger, sadness, and sexual wishes), they may respond with surprise, indignation, or denial. The results of the cognitive examination are usually normal, although they may show a lack of perseverance on arithmetic or concentration tasks, and the patients' forgetfulness of affect-laden material may be astonishing.

Narcissistic Personality Disorder. Persons with narcissistic personality disorder have a grandiose sense of self-importance; they consider themselves special and expect special treatment. Their sense of entitlement is striking. They handle criticism poorly and may become enraged when someone dares to criticize them, or they may appear utterly indifferent to criticism. Persons with this disorder want their way and are frequently ambitious to achieve fame and fortune. Their relationships are tenuous, and they can make others furious by their refusal to obey conventional rules of behavior. Interpersonal exploitativeness is commonplace. They cannot show empathy, and they feign sympathy only to achieve their selfish ends. Because of their fragile self-esteem, they are susceptible to depression. Interpersonal difficulties, occupational problems, rejection, and loss are among the stresses that narcissists commonly produce by their behavior—stresses they are least able to handle. Table 19-8 compares the different approaches to diagnosing narcissistic personality disorder.

Table 19-8
Narcissistic Personality Disorder: Specific Symptoms

DSM-5	ICD-10
Narcissistic Personality Disorder	**Narcissistic Personality**
Self-important, lacking empathy for others (≥5): • Grandiose • Preoccupied with fantasies about success • Feeling special/unique • Needing others to admire them for validation • Expecting special treatment • Exploiting others • Lacking empathy • Jealous of others' success,	Not described. Listed as an "other specific personality disorder"

| assuming others are jealous of them |
| • Arrogance |

Cluster C: Anxious

Avoidant Personality Disorder. Hypersensitivity to rejection by others is the central feature of avoidant personality disorder, and timidity is the primary personality trait that is displayed. These persons desire the warmth and security of human companionship but justify their avoidance of relationships by their fear of rejection. When talking with someone, they express uncertainty, show a lack of self-confidence, and may speak in a self-effacing manner. Because they are hypervigilant about rejection, they are afraid to speak up in public or to make requests of others. They are apt to misinterpret others' comments as derogatory or ridiculing. The refusal of any request leads them to withdraw from others and to feel hurt. Table 19-9 compares the different approaches to diagnosing avoidant personality disorder.

In the vocational sphere, patients with avoidant personality disorder often take jobs on the sidelines. They rarely attain much personal advancement or exercise much authority but seem shy and eager to please. These persons are generally unwilling to enter relationships unless they have an unusually strong guarantee of uncritical acceptance. Consequently, they often have no close friends or confidants.

In clinical interviews, patients' most striking aspect is anxiety about talking with an interviewer. Their nervous and tense manner may wax and wane depending on whether they think the interviewer likes them. They may also seem vulnerable to the interviewer's comments and suggestions and may regard a clarification or interpretation as criticism.

Dependent Personality Disorder. Dependent personality disorder is a pervasive pattern of dependent and submissive behavior. Persons with the disorder cannot make decisions without significant and unwarranted advice and encouragement from others. They avoid positions of responsibility and become anxious if asked to assume a leadership role. They prefer to be

submissive. When on their own, they find it difficult to persevere at tasks but may find it easy to perform these tasks for someone else. Table 19-10 compares the different approaches to diagnosing dependent personality disorder.

Table 19-9
Avoidant Personality Disorder: Specific Symptoms

DSM-5	ICD-10
Avoidant Personality Disorder	**Anxious [Avoidant] Personality Disorder**
Hypersensitive, lacking confidence (≥4): • Avoids others • Fears being disliked • Avoids relationships for fear of shame • Fears rejection/criticism • Inhibited in relationships • Avoids novelty for fear of embarrassment	• Fearful, insecure, feels inferior to others • Craves acceptance • Fears or is sensitive to rejection • Relationships are superficial • Avoids activities/situations perceived as risky

Table 19-10
Dependent Personality Disorder: Specific Symptoms

DSM-5	ICD-10
Dependent Personality Disorder	**Dependent Personality Disorder**
Fears separation, needs others to care for them (≥5): • Cannot make decisions alone • Avoids taking on responsibility for important things	• Relies on others and needs them for validation • Cannot make decisions without another's approval • Fears abandonment

• Cannot disagree with others for fear they will disapprove of them	• Fears helplessness/incompetence
• Lacks confidence, cannot initiate new things	• Passive, lets another make decisions
• Seeks acceptance of others	• Avoids responsibility
• Fears being alone/independence	
• When relationship ends, quickly seeks new one	
• Fears having to take care of self	

Because persons with the disorder do not like to be alone, they seek out others on whom they can depend; their relationships, thus, are distorted by their need to be attached to another person. In a shared psychotic disorder (folie à deux), one member of the pair usually has dependent personality disorder; the submissive partner takes on the delusional system of the more aggressive, assertive partner on whom he or she depends.

Pessimism, self-doubt, passivity, and fears of expressing sexual and aggressive feelings all typify the behavior of persons with a dependent personality disorder. An abusive, unfaithful, or alcoholic spouse may be tolerated for long periods to avoid disturbing the sense of attachment.

In interviews, patients appear compliant. They try to cooperate, welcome specific questions and look for guidance.

Obsessive-Compulsive Personality Disorder. Persons with obsessive-compulsive personality disorder are preoccupied with rules, regulations, orderliness, neatness, details, and the achievement of perfection. These traits account for the general constriction of the entire personality. They insist that rules be followed rigidly and cannot tolerate what they consider infractions. Accordingly, they lack flexibility and are intolerant. They are capable of prolonged work, provided it is routinized and does not require changes to which they cannot adapt. Table 19-11 compares the different approaches to diagnosing obsessive-compulsive personality disorder.

Persons with obsessive-compulsive personality disorder have limited interpersonal skills. They are formal and severe and often lack a sense of humor. They alienate those around them, are unable to compromise, and

insist that others submit to their needs. They are eager to please those whom they see as more powerful, however, and they carry out these persons' wishes in an authoritarian manner. Because they fear to make mistakes, they are indecisive and ruminate about making decisions. Although a stable marriage and occupational adequacy are common, persons with obsessive-compulsive personality disorder have few friends. Anything that threatens to upset their perceived stability or the routine of their lives can precipitate much anxiety otherwise bound up in the rituals that they impose on their lives and try to impose on others.

In interviews, patients with an obsessive-compulsive personality disorder may have a stiff, formal, and rigid demeanor. Their affect is not blunted or flat but often constricted. They lack spontaneity, and their mood is usually serious. Such patients may be anxious about not being in control of the interview. Their answers to questions are unusually detailed. The defense mechanisms they use are rationalization, isolation, intellectualization, reaction formation, and undoing.

Other Personality Disorders

Personality Change due to Another Medical Condition. This diagnosis involves a change in personality from previous patterns of behavior or an exacerbation of previous personality characteristics. Impaired control of the expression of emotions and impulses is a cardinal feature. Emotions are characteristically labile and shallow, although euphoria or apathy may be prominent. The euphoria may mimic hypomania, but genuine elation is absent, and patients may admit to not feeling happy. There is a hollow and silly ring to their excitement and facile jocularity, particularly when the frontal lobes are involved. Also associated with damage to the frontal lobes, the so-called frontal lobe syndrome, consists of prominent indifference and apathy, characterized by a lack of concern for events in the immediate environment. Temper outbursts, which can occur with little or no provocation, especially after alcohol ingestion, can result in violent behavior. The expression of impulses may include inappropriate jokes, a coarse manner, improper sexual advances, and antisocial conduct resulting in conflicts with the law, such as assaults on others, sexual misdemeanors, and shoplifting. They typically have diminished foresight, and cannot anticipate

the social or legal consequences of actions. Persons with temporal lobe epilepsy characteristically show humorlessness, hypergraphia, hyperreligiosity, and marked aggressiveness during seizures.

Table 19-11
Obsessive-Compulsive Personality Disorder: Specific Symptoms

Obsessive-Compulsive Personality Disorder		Anankastic Personality Dis	
Orderliness, perfectionism, self-control (≥4): • Attention to rules/details/order • Cannot complete things because of needing it to be perfect • Relationships neglected because of devotion to work • Inflexible thinking • Cannot part with things	• Cannot delegate • Stingy • Stubborn/rigid	• Plagued by doubt • Perfectionism, checking, attention to detail • Stubborn/rigid • Overly cautious • Unwanted thoughts or impulses, but not to the point of obsessions or compulsions	Exclusion result (• Obses comp disord

Persons with personality change due to a general medical condition have a clear sensorium. Mild disorders of cognitive function often coexist but do not amount to intellectual deterioration. Patients may be inattentive, which may account for disorders of recent memory. With some prodding, however, patients are likely to recall what they claim to have forgotten. We should suspect the diagnosis in patients who show marked changes in behavior or personality involving emotional lability and impaired impulse control, who have no history of mental disorder, and whose personality changes occur

abruptly or over a relatively brief time.

Other Specified Personality Disorder. DSM-5 reserves the category of other specified personality disorder for situations that meet the general criteria for a personality disorder, but the presentation does not fit into any of the personality disorder categories described above. Passive-aggressive personality and depressive personality are examples. A narrow spectrum of behavior or a particular trait—such as oppositionalism, sadism, or masochism—can also be classified in this category. A patient with features of more than one personality disorder but without the complete criteria of any one disorder can be assigned this classification.

Unspecified Personality Disorder. This diagnosis is like the above Other Specified Personality Disorder but is used in situations when we may choose not to indicate why the patient does not meet the criteria for a specific personality disorder. A typical example is a case in which there is not enough information to make a specific personality disorder diagnosis.

DIFFERENTIAL DIAGNOSIS

Many of the features of various personality disorders may occur during an episode of another mental disorder. Some of the personality disorders, particularly within a given cluster, may also share common features.

Paranoid Personality Disorder

Paranoid personality disorder can usually be differentiated from delusional disorder by the absence of fixed delusions. Unlike persons with schizophrenia, those with personality disorders typically lack hallucinations or formal thought disorder. However, when a brief reactive psychosis with delusions complicates the clinical picture of paranoid personality disorder, this distinction is far more complicated. Paranoid personality disorder can be distinguished from a borderline personality disorder because patients who are paranoid are rarely capable of overly involved, tumultuous relationships with others. Patients with paranoia lack the long history of antisocial behavior of persons with antisocial character. Persons with schizoid personality disorder are withdrawn and aloof and do not have paranoid ideation.

Schizoid Personality Disorder

Schizoid personality disorder differs from schizophrenia, delusional disorder, and affective disorder with psychotic features based on periods with positive psychotic symptoms, such as delusions and hallucinations, in the latter. Although patients with paranoid personality disorder share many traits with those with schizoid personality disorder, the former exhibit more social engagement, a history of aggressive verbal behavior, and a greater tendency to project their feelings onto others. If just as emotionally constricted, patients with obsessive-compulsive and avoidant personality disorders experience loneliness as dysphoric, possess a more abundant history of past object relations, and do not engage as much in autistic reverie. The chief distinction between a patient with schizotypal personality disorder and one with schizoid personality disorder is that the patient who is schizotypal is more similar to a patient with schizophrenia in oddities of perception, thought, behavior, and communication. Patients with avoidant personality disorder are isolated but do wish to participate in activities, a characteristic absent in those with schizoid personality disorder. Schizoid personality disorder is distinguished from autism spectrum disorder by more severely impaired social interactions and stereotypical behaviors and interests with autism.

Schizotypal Personality Disorder

Persons with schizotypal personality disorder can be distinguished from those with schizoid and avoidant personality disorders by the presence of oddities in their behavior, thinking, perception, and communication. Schizotypal personality disorder is difficult to distinguish from the heterogeneous group of solitary, odd children whose behavior is characterized by social isolation, eccentricity, and peculiarities in language seen in autism spectrum disorder and communication disorders. We distinguish the latter by the primacy and severity of the language disorder and accompanying compensatory efforts by the patient. Also, individuals with autism often have more severely impaired social interactions and restricted behaviors and interests than those with schizotypal disorder. Patients with schizotypal personality disorder can be distinguished from those with schizophrenia by the absence of psychosis. If psychotic symptoms do appear, they are brief and fragmentary. Patients with

paranoid personality disorder are suspicious but lack the odd behavior of patients with schizotypal personality disorder.

Antisocial Personality Disorder

Antisocial personality disorder differs from mere illegal behavior in that antisocial personality disorder involves many areas of a person's life. When illegal behavior is only for gain and does not include rigid, maladaptive, and persistent personality traits, we classify it as criminal behavior not associated with a personality disorder in DSM-5.

Many of these persons have a neurologic or mental disorder that has been either overlooked or undiagnosed. More difficult is the differentiation of antisocial personality disorder from substance use disorders. When both substance use disorders and antisocial behavior begin in childhood and continue into adult life, we should diagnose both disorders. When, however, the antisocial behavior is secondary to premorbid alcohol use disorder or another substance use disorder, the diagnosis of antisocial personality disorder is not warranted.

In diagnosing antisocial personality disorder, clinicians must adjust for the distorting effects of socioeconomic status, cultural background, and sex. Furthermore, the diagnosis of antisocial personality disorder is not warranted when intellectual disability, schizophrenia, or mania can explain the symptoms. Other personality disorders, such as narcissistic, histrionic, and paranoid, can be differentiated from antisocial personality disorder as the former personality disorders rarely include serious criminality and aggressiveness. Borderline personality disorder can sometimes be associated with criminality. However, individuals with borderline personality who commit crimes tend to display high novelty seeking and high harm avoidance behaviors, whereas those with antisocial personality tend to display high novelty seeking and low harm avoidance behaviors.

Borderline Personality Disorder

Borderline personality disorder differs from major depressive disorder, bipolar disorder, dysthymic disorder, and cyclothymia based on the presence of core borderline personality symptoms that are not typically present in mood disorders (e.g., fear of abandonment, highly unpredictable behavior,

tumultuous interpersonal relationships, seeing others as either all good or all bad, complaints of being numb or empty, and the lack of a consistent sense of identity). It differs from identity problems, which are typically limited to a developmental stage.

Borderline personality disorder differs from schizophrenia on the basis that the patient with borderline personality lacks prolonged psychotic episodes, thought disorder, and other classic schizophrenic signs. Patients with schizotypal personality disorder show marked peculiarities of thinking, strange ideation, and recurrent ideas of reference. Those with paranoid personality disorder have extreme suspiciousness. In contrast, patients with borderline personality disorder generally have short-lived psychotic episodes, when present.

Histrionic Personality Disorder

Distinguishing between histrionic personality disorder and borderline personality disorder is challenging, but in borderline personality disorder, suicide attempts, identity diffusion, and brief psychotic episodes are more likely. Although both conditions can exist in the same patient, clinicians should separate the two. Somatic symptom disorder may occur in conjunction with histrionic personality disorder, and we should diagnose both as well. Patients with brief psychotic disorder and dissociative disorders may warrant a coexisting diagnosis of histrionic personality disorder.

Narcissistic Personality Disorder

Borderline, histrionic, and antisocial personality disorders often accompany narcissistic personality disorder, so differential diagnosis is difficult. Patients with narcissistic personality disorder have less anxiety than those with borderline personality disorder; their lives tend to be less chaotic, and they are less likely to attempt suicide. Patients with antisocial personality disorder have a history of impulsive behavior, often associated with alcohol or other substance use, which frequently gets them into trouble with the law. Patients with histrionic personality disorder show features of exhibitionism and interpersonal manipulativeness that resemble those of patients with narcissistic personality disorder. Narcissistic personality disorder can be distinguished from the grandiosity of mania by the episodic course,

associated euphoria, and functional impairment in a manic or hypomanic episode.

Avoidant Personality Disorder

Avoidant personality disorder is complicated to distinguish from social anxiety disorder. In social anxiety disorder, specific situations, rather than interpersonal contact in general, are avoided. They may co-occur. Panic disorder with agoraphobia also manifests avoidance, but usually after the onset of panic attacks.

Patients with schizoid and schizotypal personality disorders may be indistinguishable from those with avoidant personality disorder. However, patients with avoidant personality disorder desire social interaction, unlike patients with schizoid personality disorder, who want to be alone. Patients with avoidant personality disorder are not as demanding, irritable, or unpredictable as those with borderline and histrionic personality disorders. Avoidant personality disorder and dependent personality disorder are similar. Patients with dependent personality disorder are presumed to have a greater fear of being abandoned or unloved than those with avoidant personality disorder, but the clinical picture may be indistinguishable.

Dependent Personality Disorder

The traits of dependence occur in many psychiatric disorders, so the differential diagnosis is difficult. Dependence is a prominent factor in patients with histrionic and borderline personality disorders. However, those with dependent personality disorder usually have a long-term relationship with one person rather than a series of persons on whom they are dependent, and they do not tend to be overly manipulative. Dependent behavior can also occur in patients with agoraphobia, panic disorder, and depressive disorders, but these patients tend to have a high level of overt anxiety, panic, or depression, respectively.

Obsessive-Compulsive Personality Disorder

When recurrent obsessions or compulsions are present, we should diagnose an obsessive-compulsive disorder. Perhaps the most challenging distinction is between outpatients with some obsessive-compulsive traits and those with an

obsessive-compulsive personality disorder. We should reserve the personality disorder diagnosis for those with significant impairments in their occupational or social effectiveness. In some cases, delusional disorder coexists with personality disorders, and we should diagnose both.

Personality Change due to Another Medical Condition

Dementia involves global deterioration in intellectual and behavioral capacities, of which personality change is just one category. A personality change may herald a cognitive disorder that eventually will deteriorate into dementia. In these cases, as deterioration begins to encompass significant memory and cognitive deficits, the diagnosis of the disorder changes from personality change caused by a general medical condition to dementia. In differentiating the specific syndrome from other disorders in which personality change may occur—such as schizophrenia, delusional disorder, mood disorders, and impulse control disorders—physicians must consider the most critical factor, the presence of a personality change due to a specific organic causative factor.

COMORBIDITY

Personality disorders occur in 10 to 20 percent of the general population and about half of psychiatric inpatients or outpatients. Personality disorders are frequently comorbid with other clinical syndromes and are predisposing factors for other psychiatric disorders and symptoms (e.g., substance use, suicide, affective disorders, impulse-control disorders, eating disorders, and anxiety disorders).

Paranoid Personality Disorder

These individuals are at increased risk for major depression, obsessive-compulsive disorder, agoraphobia, and substance use disorders. The most common co-occurring personality disorders are schizotypal, schizoid, narcissistic, avoidant, and borderline. Paranoid personality disorder may be a premorbid antecedent of delusional disorder, persecutory type.

Schizoid Personality Disorder

This personality disorder sometimes appears as the premorbid antecedent of delusional disorder, schizophrenia, or rarely major depression. Paranoid, schizotypal, and avoidant are the most common co-occurring personality disorders.

Schizotypal Personality Disorder

More than half of these patients have had at least one episode of major depression, and 30 to 50 percent have major depression concurrent with this personality disorder. The most common co-occurring personality disorders are schizoid, paranoid, avoidant, and borderline.

Antisocial Personality Disorder

These patients are at increased risk for impulse control disorders, major depression, substance use disorders, pathologic gambling, anxiety disorders, and somatic symptom disorder. Narcissistic, borderline, and histrionic are the most common co-occurring personality disorders.

Borderline Personality Disorder

These individuals are at increased risk for major depression, substance use disorders, eating disorders (notably bulimia), posttraumatic stress disorder, attention-deficit hyperactivity disorder, and somatic symptom disorder. Borderline personality disorder can co-occur with most other personality disorders.

Histrionic Personality Disorder

Patients with histrionic personality disorder are at increased risk for major depression, somatic symptom disorder, and conversion disorder. Narcissistic, borderline, antisocial, and dependent are the most common co-occurring personality disorders.

Narcissistic Personality Disorder

These patients are at increased risk for major depression and substance use disorders (especially cocaine use). The most common co-occurring personality disorders are borderline, antisocial, histrionic, and paranoid.

Avoidant Personality Disorder

Patients with avoidant personality disorder are at increased risk for mood and anxiety disorders (especially social anxiety disorder). The most common co-occurring personality disorders are schizotypal, schizoid, paranoid, dependent, and borderline. Somatic symptom disorder may be comorbid.

Dependent Personality Disorder

These patients are at increased risk for major depression, anxiety disorders, and adjustment disorder. Somatic symptom disorder may be comorbid. The personality disorders that co-occur most commonly are histrionic, avoidant, and borderline.

Obsessive-Compulsive Personality Disorder

These individuals are at increased risk for major depression and anxiety disorder. Equivocal evidence exists for an increased risk of obsessive-compulsive disorder.

COURSE AND PROGNOSIS

Personality disorders are chronic, and they last over decades. They often interfere with the treatment outcomes of comorbid psychiatric disorders and lead to personal incapacitation, morbidity, and mortality in these patients. People with personality disorders have chronic impairments in their ability to work and love, tend to be less educated, drug dependent, single, unemployed, and to have marital difficulties. They consume a large portion of community services, social welfare benefits, public health, and prison resources.

Paranoid Personality Disorder

There are no adequate, systematic long-term studies of paranoid personality disorder. In some, paranoid personality disorder is lifelong; in others, it is a harbinger of schizophrenia. In still others, paranoid traits give way to reaction formation, appropriate concern with morality, and altruistic concerns as they mature or as stress diminishes. In general, however, those with paranoid personality disorder have lifelong problems working and living with others.

Occupational and marital problems are common. Complications may

include brief reactive psychosis, particularly in response to stress.

Schizoid Personality Disorder

The onset of schizoid personality disorder usually occurs in early childhood or adolescence. As with all personality disorders, schizoid personality disorder is long-lasting but not necessarily lifelong. The proportion of patients who incur schizophrenia is unknown. These individuals frequently have severe problems in social relations, and occupational problems develop when interpersonal involvement is required. Solitary work sometimes favorably affects overall performance. Complications may include very brief reactive psychosis, particularly in response to stress.

Schizotypal Personality Disorder

This disorder can be the premorbid personality of the patient with schizophrenia. Some, however, maintain a stable schizotypal personality throughout their lives and marry and work, despite their oddities. Complications may include transient psychotic episodes, particularly in response to stress. Symptoms sometimes become so significant that individuals meet the criteria for schizophreniform disorder, delusional disorder, and brief psychotic disorder. One long-term study reported that 10 percent of those with schizotypal personality disorder eventually committed suicide.

Antisocial Personality Disorder

When an antisocial personality disorder develops, it runs an unremitting course, with the height of antisocial behavior usually occurring in late adolescence. The prognosis varies. Some reports indicate that symptoms decrease as a person ages. Even after the severe antisocial behavior "burns out," people diagnosed with antisocial personality disorder usually continue to be irritable, impulsive, and detached. Complications may include dysphoria, tension, low tolerance for boredom, depressed mood, and premature, violent death.

Borderline Personality Disorder

The course of borderline personality disorder is variable and most commonly

follows a pattern of chronic instability in early adulthood, with episodes of severe affective and impulsive dyscontrol. The impairment and the risk of suicide are highest in the young adult years and gradually wane with advancing age. In the fourth and fifth decades, these individuals tend to attain greater stability in their relationships and functioning. Impairment typically involves frequent job losses, interrupted education, and broken marriages. Complications may include psychotic-like symptoms (hallucinations, body image distortions, hypnagogic phenomena, ideas of reference) in response to stress, as well as premature death or physical handicaps from suicide and suicidal gestures, failed suicide, and self-injurious behavior.

Histrionic Personality Disorder

With age, persons with histrionic personality disorder show fewer symptoms, but because they lack the energy of earlier years, the difference in the number of symptoms may be more apparent than real. Persons with this disorder are sensation seekers, and they may get into trouble with the law, abuse substances, and act promiscuously. Complications may include frequent suicidal gestures and threats to coerce better caregiving; interpersonal relations that are unstable, shallow, and generally ungratifying; and frequent marital problems secondary to the tendency to neglect long-term relationships for the excitement of new relationships.

Narcissistic Personality Disorder

Narcissistic personality disorder is chronic and difficult to treat. Patients with the disorder must continuously deal with blows to their narcissism resulting from their behavior or life experience. Patients handle aging poorly; they value beauty, strength, and youthful attributes, to which they cling inappropriately. They may be more vulnerable, therefore, to midlife crises than are other groups. However, narcissistic symptoms tend to diminish after the age of 40 years, when pessimism usually develops. Impairment is frequently severe and includes marital problems and interpersonal relationships in general. Complications may include social withdrawal, depressed mood, and dysthymic or major depressive disorder in reaction to criticism or failure.

Avoidant Personality Disorder

Avoidant personality disorder frequently begins in childhood with shyness and fear of strangers and new situations. Impairment can be severe and typically includes occupational and social difficulties. However, many persons with avoidant personality disorder can function in a protected environment. Some marry, have children, and live their lives surrounded only by family members. If their support system fails, however, they are subject to depression, anxiety, and anger. Phobic avoidance is common, and patients with the disorder may give histories of social anxiety disorder or incur social anxiety disorder in the course of their illness.

Dependent Personality Disorder

We know little about the course of dependent personality disorder. Occupational functioning tends to be impaired because persons with the disorder cannot act independently and without close supervision. Social relationships are limited to those on whom they can depend, and many suffer physical or mental abuse because they cannot assert themselves. They risk major depressive disorder if they lose the person on whom they depend, but with treatment, the prognosis is favorable. Complications may include low socioeconomic status and inadequate family and marital functioning, as well as mood disorders, anxiety disorders, adjustment disorder, and social anxiety disorder.

Obsessive-Compulsive Personality Disorder

The course of obsessive-compulsive personality disorder is variable and unpredictable. Occupational and social difficulties are typical. From time to time, persons may develop obsessions or compulsions in the course of their disorder. Some adolescents with obsessive-compulsive personality disorder evolve into warm, open, and loving adults; in others, the disorder can be either the harbinger of schizophrenia or—decades later and exacerbated by the aging process—major depressive disorder.

Persons with obsessive-compulsive personality disorder may flourish in positions demanding methodical, deductive, or detailed work, but they are vulnerable to unexpected changes, and their personal lives may remain barren. Depressive disorders, especially those of late-onset, are common.

Complications may include distress and difficulties when confronted with new situations that require flexibility and compromise, as well as myocardial infarction secondary to features typical of type A personalities, such as time urgency, hostility, and competitiveness.

Personality Change due to Another Medical Condition

Both the course and the prognosis of personality change due to a general medical condition depend on its cause. If the disorder results from structural damage to the brain, the disorder tends to persist. In cases of head trauma or vascular accident, the disorder may follow a period of coma and delirium, and it may be permanent. The personality change can evolve into dementia in cases of brain tumors, multiple sclerosis, and Huntington disease. Personality changes produced by chronic intoxication, medical illness, or drug therapy (such as levodopa for parkinsonism) may reverse with appropriate treatment of the cause. Some patients require custodial care or at least close supervision to meet their basic needs, avoid repeated conflicts with the law, and protect themselves and their families from the hostility of others and destitution resulting from impulsive and ill-considered actions.

TREATMENT APPROACH

Individuals with personality disorders do not recognize that they are ill and seldom seek help unless others (such as a spouse or parents) are insistent. This usually happens when maladaptive behaviors create marital, family, and career problems, or when other disorders (e.g., anxiety, depression, substance use) or somatic symptoms (e.g., obesity, heart disease, COPD) complicate their clinical picture. In general, patients with personality disorders require a multifaceted treatment plan that often combines psychotherapy and pharmacotherapy.

Combining Psychotherapy and Pharmacotherapy

Most patients with a personality disorder will require a combination of psychotherapy and pharmacotherapy. Psychotherapy is the primary treatment, as it promotes the maturation of character and, ultimately, the encouragement of the patient's capacity to develop better adaptive solutions. However,

psychotherapy is very hard to implement in the setting of unstable affect and risky or self-destructive behaviors, all very common in the initial stages of treatment. During these early stages, pharmacotherapy achieves a relatively prompt control of affect and behavior. Most importantly, this nonspecific improvement sets a more suitable platform for the work in psychotherapy.

Pharmacotherapy. In the treatment of patients with personality disorders, medications can target specific symptoms of their disorders with the goals of relieving subjective distress, risky or self-destructive behaviors, or conflict with others, thereby preparing them for or allowing them to participate in psychotherapeutic approaches. We should identify target symptoms, in order to choose agents that effect those symptoms. Table 19-12 summarizes drug choices for various target symptoms of personality disorders.

Paranoid Personality Disorder

Psychotherapy. Psychotherapy is the treatment of choice for those with paranoid personality disorder. Therapists should be straightforward in all their dealings with these patients. If the patient accuses the therapist of an inconsistency or a fault, such as lateness for an appointment, honesty and an apology are preferable to a defensive explanation. Therapists must remember that trust and tolerance of intimacy are troubled areas for patients with this disorder. Individual psychotherapy thus requires a professional and not overly warm style from therapists. Clinicians' overzealous use of interpretation—especially interpretation about deep feelings of dependence, sexual concerns, and wishes for intimacy—increases patients' mistrust significantly. Generally, patients who are paranoid do not do well in group psychotherapy, although it can be useful for improving social skills and diminishing suspiciousness through role-playing. Many cannot tolerate the intrusiveness of behavior therapy, also used for social skills training.

At times, patients with paranoid personality disorder behave so threateningly that therapists must control or set limits on their actions. Delusional accusations should be realistically handled, but gently and without humiliating patients. Patients who are paranoid are profoundly frightened when they feel that those trying to help them are weak and helpless; therefore, therapists should never offer to take control unless they are willing

and able to do so.

Pharmacotherapy. There is little evidence to guide the use of pharmacotherapy in paranoid personality disorder. Treatment selection should be tailored to the individual patient and guided by target symptoms, such as the use of low-dose novel antipsychotics for psychotic symptoms or the use of anticonvulsants for irritability.

Schizoid Personality Disorder

Psychotherapy. The treatment of patients with schizoid personality disorder is similar to that of those with paranoid personality disorder. Patients who are schizoid tend toward introspection; however, these tendencies are consistent with psychotherapists' expectations, and such patients may become devoted if distant patients. As trust develops, patients who are schizoid may, with great trepidation, reveal a plethora of fantasies, imaginary friends, and fears of unbearable dependence—even of merging with the therapist.

In group therapy settings, patients with schizoid personality disorder may be silent for long periods; nonetheless, they do become involved. The patients should be protected against aggressive attack by group members for their proclivity to be silent. With time, the group members become important to patients who are schizoid and may provide the only social contact in their otherwise isolated existence.

Pharmacotherapy. Limited evidence exists to guide the psychopharmacologic treatment of patients with schizoid personality disorder. The use of psychotropics to target specific symptoms, such as social and emotional detachment, may be appropriate.

Schizotypal Personality Disorder

Psychotherapy. The principles of treatment of schizotypal personality disorder do not differ from those of schizoid personality disorder, but clinicians must deal sensitively with the former, mainly using care to avoid ridiculing or judging patients' odd beliefs. Schizotypal patients have peculiar

patterns of thinking, and some are involved in cults, strange religious practices, or the occult.

Pharmacotherapy. Antipsychotic medication may be useful for dealing with ideas of reference, illusions, and other symptoms of the disorder and can be an adjunct to psychotherapy. Antidepressants are useful when a depressive component of the personality is present.

Antisocial Personality Disorder

Psychotherapy. There is limited evidence to guide the use of psychotherapeutic approaches in antisocial personality disorder. Overall, the limited evidence suggests that these individuals seem to respond better to contingency management and other reward-based interventions than they do to cognitive behavioral therapy.

Pharmacotherapy. Pharmacotherapy can deal with incapacitating symptoms such as anxiety, rage, and depression, but because patients often misuse substances, we should use medications judiciously. One might use anticonvulsants to treat aggressive behaviors, especially if there are abnormal waveforms on an EEG. β-Adrenergic receptor antagonists, lithium, and antipsychotics may also reduce aggression.

Borderline Personality Disorder

Psychotherapy. Psychotherapy for patients with borderline personality disorder is an area of intensive investigation and has been the treatment of choice. It seems to be most successful in combination with pharmacotherapy.

Psychotherapy is difficult for the patient and therapist alike. Patients regress quickly, act out their impulses, and show labile or fixed negative or positive transferences, which are difficult to analyze. Projective identification may also cause countertransference problems when therapists are unaware that patients are unconsciously trying to coerce them to act out a particular behavior. The splitting defense mechanism causes patients to love and hate therapists and others in the environment alternately. A reality-oriented approach is more effective than in-depth interpretations of the unconscious.

Table 19-12
Pharmacotherapy of Target Symptom Domains of Personality Disorders

Choice of Drugs According to Target Symptoms of Personality Disorders		
Target Symptom	**Drug/Treatment of Choice**	**Not Recommended**
I. Mood Dysregulation and Anxiety		
Anxiety		
Chronic cognitive	Psychotherapy, SSRIs, SNRIs, MAOIs, Low-Dose Novel Psychotropics (aripiprazole, quetiapine) Valproate and other GABA analogs (clonazepam and buspirone)	Benzodiazepines
Chronic somatic	MAOIs, SNRIs (duloxetine, milnacipran) Pregabalin and other GABA analogs, TCAs, beta-blockers	If used— benzodiazepines with long half- and short trials preferred
Obsessions	SSRIs, Antipsychotics (quetiapine), TCAs (clomipramine), Mild NMDA antagonists	

	(riluzole, memantine)	
Acute and severe	Mirtazapine, Novel Psychotropics (quetiapine, aripiprazole, clozapine), TCAs, clonazepam, valproates, lithium	

Depression

Atypical depression/dysphoria Classical depression	MAOIs, SSRIs, SNRIs, Aripiprazole, Lurasidone, ziprasidone, quetiapine, Atypical antipsychotics (as monotherapy or augmentation)	TCAs
Emotional lability/rapid cycling	Lithium, Lamotrigine, Valproate, Lower-dose antipsychotics (olanzapine, aripiprazole, clozapine, ziprasidone)	TCAs ("catecholami stress"), Standard antidepressan (risk of switchi to mania)

II. Behavior Dyscontrol

Aggression/impulsivity

Affective aggression "Hot temper" with normal	Lithium, SSRIs, Anticonvulsants,	Benzodiazepines (disinhibition)

EEG	Low-dose antipsychotics	
Predatory aggression (cold blooded revenge/cruelty)	No Effective Pharmacologic Tx	Benzodiazepines (disinhibition)
Organic-like aggression (traumatic brain injury)	Beta-Blockers, Valproates, Quetiapine, Carbamazepine (CBMZ), TCAs, cholinesterase inhibitors (donepezil)	Benzodiazepines (disinhibition, delirium)
Ictal aggression (abnormal EEG)	CBMZ, Diphenylhydantoin, Valproate Benzodiazepines (clonazepam)	TCAs, Low-potency typical antipsychotics (both increase risk of seizure)

III. Social and Emotional Detachment

Chronic asociality and disinterest		
Blunted affect	Low-Dose Antipsychotics (aripiprazole, olanzapine, low-dose clozapine, sulpiride)	

IV. Cognitive-Perceptual Distortions/Psychotic Symptoms

Acute and brief psychotic episodes	Novel Antipsychotics (Risperdal, olanzapine)	
	Typical neuroleptics (for the duration of	

	psychosis)
Chronic and low-level psychotic-like symptoms	Novel Antipsychotics

Therapists have used behavior therapy to help patients manage their impulses and angry outbursts and to reduce their sensitivity to criticism and rejection. Social skills training, especially with videotape playback, helps patients to see how their actions affect others and thereby improve their interpersonal behavior.

Patients with borderline personality disorder often do well in a hospital setting in which they receive intensive psychotherapy on both an individual and a group basis. In a hospital, they can also interact with trained staff members from a variety of disciplines and receive occupational, recreational, and vocational therapy. Such programs are especially helpful when the home environment is detrimental to a patient's rehabilitation because of intrafamilial conflicts or other stresses, such as abuse. Within the protected environment of the hospital, we can give limits to patients who are excessively impulsive, self-destructive, or self-mutilating, and observe their actions. Under ideal circumstances, patients remain in the hospital until they show marked improvement, up to 1 year in some cases. We can then discharge patients to specialized support systems, such as day hospitals, night hospitals, and halfway houses.

DIALECTICAL BEHAVIOR THERAPY. Dialectical behavior therapy (DBT) is the psychosocial treatment that has received the most empirical support for patients with borderline personality disorder. The method is eclectic, drawing on concepts derived from supportive, cognitive, and behavioral therapies. There are four primary modes of treatment in DBT: group skill training, individual therapy, phone consultation, and consultation team. Patients are seen weekly, with the goal of improving interpersonal skills and decreasing self-destructive behavior. Patients with borderline personality disorder receive help in dealing with the ambivalent feelings that are characteristic of the disorder. As with other behavioral approaches, DBT assumes all behavior

(including thoughts and feelings) is learned and that patients with borderline personality disorder behave in ways that reinforce or even reward their behavior, regardless of how maladaptive it is. See Chapter 23 for a more detailed discussion of DBT.

MENTALIZATION-BASED TREATMENT. Another type of psychotherapy for borderline personality disorder is called mentalization-based therapy (MBT). Mentalization is a social construct that allows a person to be attentive to the mental states of oneself and of others; it comes from a person's awareness of mental processes and subjective states that arise in interpersonal interactions. MBT is based on a theory that borderline personality symptoms, such as difficulty regulating emotions and managing impulsivity, are a result of patients' reduced capacities to mentalize. Thus, recovery of mentalization should help patients build relationship skills as they learn to regulate their thoughts and feelings better. MBT was effective for borderline personality disorder in several randomized, controlled research trials.

TRANSFERENCE-FOCUSED PSYCHOTHERAPY. Transference-focused psychotherapy (TFP) is a modified form of psychodynamic psychotherapy used for the treatment of borderline personality disorder grounded in object relations theory. The therapist relies on two major processes in working with the patient: the first is clarification, in which the transference is analyzed more directly than in traditional psychotherapy so that the patient becomes quickly aware of his or her distortions about the therapist, and the second is confrontation, whereby the therapist points out how these transferential distortions interfere with interpersonal relations toward others (objects). The mechanism of splitting used by borderline patients is characterized by their having a good object and a bad object, and they use this as a defense against anxiety. If therapy is successful, then the need for splitting diminishes, object relations are improved, and the patient achieves a more normal level of functioning. Studies comparing TFP, DBT, psychodynamic psychotherapy, and supportive psychotherapy show that all are useful and all show varying degrees of success.

Pharmacotherapy. Pharmacotherapy is useful to deal with specific personality features that interfere with patients' overall functioning.

Antipsychotics may help control anger, hostility, and brief psychotic episodes. Antidepressants improve the depressed mood common in patients with borderline personality disorder. Benzodiazepines should be avoided not only due to the risk of abuse, but also because patients may become disinhibited with this class of drugs. Anticonvulsants, such as carbamazepine, may improve functioning for some patients. Serotonergic agents, such as selective serotonin reuptake inhibitors (SSRIs), have been helpful in some cases.

Histrionic Personality Disorder

Psychotherapy. Patients with histrionic personality disorder are often unaware of their real feelings; clarification of their inner feelings is a necessary therapeutic process. Psychoanalytically oriented psychotherapy is probably the treatment of choice for histrionic personality disorder.

Pharmacotherapy. Pharmacotherapy can be adjunctive to target symptoms (e.g., the use of antidepressants for depression and somatic complaints, antianxiety agents for anxiety, and antipsychotics for derealization and illusions).

Narcissistic Personality Disorder

Psychotherapy. Because patients must renounce their narcissism to make progress, the treatment of narcissistic personality disorder is challenging. Some experts have advocated using psychoanalytic approaches to effect change, but much research is required to validate the diagnosis and to determine the best treatment. Some clinicians advocate group therapy for their patients so they can learn how to share with others and, under ideal circumstances, can develop an empathic response to others.

Pharmacotherapy. Lithium can help patients whose clinical picture includes mood swings. Because patients with narcissistic personality disorder tolerate rejection poorly and are susceptible to depression, antidepressants, especially serotonergic drugs, may also be of use.

Avoidant Personality Disorder

Psychotherapy. Psychotherapeutic treatment depends on solidifying an alliance with patients. As trust develops, a therapist must convey an accepting attitude toward the patient's fears, especially the fear of rejection. The therapist eventually encourages a patient to move out into the world to take what they perceive as significant risks of humiliation, rejection, and failure. However, therapists should be cautious when giving assignments to exercise new social skills outside therapy; failure can reinforce the patient's already weak self-esteem. Group therapy may help patients understand how their sensitivity to rejection affects them and others. Assertiveness training is a form of behavior therapy that may teach patients to express their needs openly and to enlarge their self-esteem.

Pharmacotherapy. Pharmacotherapy can help manage anxiety and depression when they are associated with the disorder. Some patients are helped by β-adrenergic receptor antagonists, such as atenolol, to manage autonomic nervous system hyperactivity, which tends to be high in patients with avoidant personality disorder, especially when they approach feared situations. Serotonergic agents may help with rejection sensitivity. Theoretically, dopaminergic drugs might engender novelty-seeking behavior in these patients; however, the patient must be psychologically prepared for any new experience that might result.

Dependent Personality Disorder

Psychotherapy. The treatment of dependent personality disorder is often successful. Insight-oriented therapies enable patients to understand the antecedents of their behavior, and with the support of a therapist, patients can become more independent, assertive, and self-reliant. Behavioral therapy, assertiveness training, family therapy, and group therapy have all been used, with successful outcomes in many cases.

A pitfall may arise in treatment when a therapist encourages a patient to change the dynamics of a pathologic relationship (e.g., supports a physically abused wife in seeking help from the police). At this point, patients may become anxious and unable to cooperate in therapy; they may feel torn

between complying with the therapist and losing an external pathologic relationship. Therapists must show great respect for these patients' feelings of attachment, no matter how pathologic these feelings may seem.

Pharmacotherapy. Pharmacotherapy can help deal with specific symptoms, such as anxiety and depression, which are commonly associated features of dependent personality disorder. Patients who experience panic attacks or who have high levels of separation anxiety may benefit from symptom-targeted pharmacotherapy, such as antidepressant agents.

Obsessive-Compulsive Personality Disorder

Psychotherapy. Unlike patients with other personality disorders, some individuals with obsessive-compulsive personality disorder are often aware of their suffering and seek treatment on their own. Though limited evidence exists to guide treatment, there have been several studies that support cognitive therapy or cognitive behavioral therapy as an effective treatment for individuals with this disorder, delivered either individually or in a group. Additionally, interpersonal psychotherapy may improve depressive symptoms in individuals with obsessive-compulsive personality disorder.

Pharmacotherapy. There is limited evidence for the pharmacologic treatment of obsessive-compulsive personality disorder. Some studies have suggested benefits from fluvoxamine and carbamazepine, and in those patients with comorbid depression, citalopram may be helpful. In one study comparing citalopram and sertraline, both medications reduced the number of obsessive-compulsive personality disorder traits, though citalopram performed better than sertraline.

Personality Change due to Another Medical Condition

Management of personality change disorder involves the treatment of the underlying medical condition when possible. Psychopharmacological treatment of specific symptoms may help in some cases, such as antidepressants for depression or anticonvulsants for irritability, aggression, or impulsivity.

Patients with severe cognitive impairment or weakened behavioral controls

may need counseling to help avoid difficulties at work or to prevent social embarrassment. As a rule, patients' families need emotional support and concrete advice on how to help minimize patients' undesirable conduct. Patients should avoid alcohol, and we should curtail social engagements when patients tend to act in a grossly offensive manner.

EPIDEMIOLOGY

Personality disorders are common. They occur in 10 to 20 percent of the general population, and approximately 50 percent of all psychiatric patients.

Paranoid Personality Disorder

Data suggest that the prevalence of paranoid personality disorder is 0.5 to 4.4 percent of the general population. Those with the disorder rarely seek treatment themselves; when referred to treatment by a spouse or an employer, they can often pull themselves together and appear undistressed. Relatives of patients with schizophrenia show a higher incidence of paranoid personality disorder than control participants. Some evidence suggests a more specific familial relationship with delusional disorder, persecutory type. The diagnosis is more common in men.

Schizoid Personality Disorder

The prevalence of schizoid personality disorder is estimated to be 3.1 to 4.9 percent of the general population, according to DSM-5. This diagnosis is more common in men. Persons with the disorder tend to gravitate toward solitary jobs that involve little or no contact with others. Many prefer night work to day work so that they need not deal with many persons. There appears to be an increased prevalence among the relatives of individuals with schizophrenia or schizotypal personality disorder.

Schizotypal Personality Disorder

Schizotypal personality disorder occurs in 3.9 to 4.6 percent of the population, according to DSM-5. The sex ratio is unknown; however, it is frequent in females with fragile X syndrome. A higher association of cases exists among the biologic relatives of patients with schizophrenia than among

control participants and a higher incidence among monozygotic twins than among dizygotic twins (33 percent vs. 4 percent in one study).

Antisocial Personality Disorder

According to DSM-5, prevalence rates for antisocial personality disorder are 3 percent for males and 1 percent for females in the general population. It is frequent among the first-degree biologic relatives of individuals with this disorder. Biologic relatives of females with antisocial personality disorder are at increased risk for the same disorder compared to biologic relatives of males with antisocial personality disorder. Genetic studies have suggested familial transmission of antisocial personality disorder, substance use, and somatic symptom disorder (most studies used the previous criteria for the related somatization disorder), the former two being characteristic of males, and the latter of females in the same family. Adoption studies have shown that both genetic and environmental factors contribute to the risk of this disorder. Both adopted and biologic children of parents with antisocial personality disorder are at increased risk for this disorder. Conduct disorder (before the age of 10 years) and accompanying attention-deficit hyperactivity disorder increases the likelihood of developing antisocial personality in adult life. Conduct disorder is more likely to develop into antisocial personality disorder with erratic parenting, neglect, or inconsistent parental discipline.

Borderline Personality Disorder

Borderline personality disorder is thought to be present in about 2 percent of the general population and is more common in women than in men. The disorder is more common in younger than in older samples, suggesting a natural tendency toward maturation and remission. Physical and sexual abuse, neglect, hostile conduct, and early parental loss or separation are common in the childhood histories of patients with this disorder. Borderline personality disorder is five times more common among relatives of individuals with the same disorder than the general population. An increased prevalence of mood disorders, antisocial personality disorder, and substance use disorder is common in first-degree relatives of persons with borderline personality disorder.

Histrionic Personality Disorder

Limited data from general population studies suggest a prevalence of histrionic personality disorder of about 2 percent. Although traditionally thought to occur more frequently in women, there is some evidence to suggest that this disorder might be equally frequent among men and women. Histrionic personality disorder tends to run in families. Some experts suggest that there is a genetic link between histrionic and antisocial personality disorder and alcohol use disorder.

Narcissistic Personality Disorder

According to DSM-5, estimates of the prevalence of narcissistic personality disorder range from less than 1 percent in the general population to 2 to 16 percent in the clinical population; this disorder is more common in men.

Avoidant Personality Disorder

The prevalence of the disorder is about 0.5 to 2 percent of the general population, according to DSM-5. It occurs in men and women equally.

Dependent Personality Disorder

Dependent personality disorder is equally common in women and men. DSM-5 reports an estimated prevalence of 0.5 to 0.6 percent. Persons with chronic physical illness in childhood or separation anxiety disorder may be most susceptible to dependent personality disorder.

Obsessive-Compulsive Personality Disorder

DSM-5 reports an estimated prevalence ranging from 2 to 8 percent of the general population. It is more common in men than in women. Some studies have demonstrated a familial aggregation of this disorder.

ETIOLOGY

Genetic Factors

The best evidence that genetic factors contribute to personality disorders comes from investigations of more than 15,000 pairs of twins in the United

States. The concordance for personality disorders among monozygotic twins was several times that among dizygotic twins. Moreover, according to one study, monozygotic twins reared apart are about as similar as monozygotic twins reared together. Similarities include multiple measures of personality and temperament, occupational and leisure-time interests, and social attitudes.

Cluster A personality disorders are more common in the biologic relatives of patients with schizophrenia than in control groups. Adoption, family, and twin studies demonstrate an increased prevalence of schizotypal features in the families of schizophrenic patients, mainly when schizotypal features were not associated with comorbid affective symptoms. Less correlation exists between paranoid or schizoid personality disorder and schizophrenia.

Cluster B personality disorders have a genetic basis. Antisocial personality disorder is associated with alcohol use disorders. Depression is common in the family backgrounds of patients with borderline personality disorder. These patients have more relatives with mood disorders than do control groups, and persons with borderline personality disorder often have a mood disorder as well. There is a strong association between histrionic personality disorder and somatic symptom disorder; patients with each disorder show an overlap of symptoms.

Cluster C personality disorders may also have a genetic base. Patients with avoidant personality disorder often have high anxiety levels. Obsessive-compulsive traits are more common in monozygotic twins than in dizygotic twins, and patients with obsessive-compulsive personality disorder show some signs associated with depression—for example, shortened rapid eye movement (REM) latency period and abnormal dexamethasone-suppression test (DST) results.

Biologic Factors

Hormones. Persons who exhibit impulsive traits also often show high levels of testosterone, 17-estradiol, and estrone. In nonhuman primates, androgens increase the likelihood of aggression and sexual behavior, but the role of testosterone in human aggression is unclear. DST results are abnormal in some patients with borderline personality disorder who also have depressive symptoms.

Platelet Monoamine Oxidase. Low platelet monoamine oxidase (MAO) levels are associated with activity and sociability in monkeys. College students with low platelet MAO levels report spending more time in social activities than students with high platelet MAO levels. Low platelet MAO levels occur in some patients with schizotypal disorders.

Smooth Pursuit Eye Movements. Smooth pursuit eye movements are saccadic (i.e., jumpy) in persons who are introverted, who have low self-esteem and tend to withdraw, and who have schizotypal personality disorder. These findings have no clinical application, but they do indicate the role of inheritance.

Neurotransmitters. Studies of personality traits and the dopaminergic and serotonergic systems indicate an arousal-activating function for these neurotransmitters. Levels of 5-hydroxyindoleacetic acid (5-HIAA), a metabolite of serotonin, are low in persons who attempt suicide and in patients who are impulsive and aggressive. Raising serotonin levels with serotonergic agents such as fluoxetine can produce dramatic changes in some character traits of personality. In many persons, serotonin reduces depression, impulsiveness, and rumination and can produce a sense of general well-being. Increased dopamine concentrations in the central nervous system produced by certain psychostimulants (e.g., amphetamines) can induce euphoria. The effects of neurotransmitters on personality traits have generated much interest and controversy about whether personality traits are inborn or acquired.

Table 19-13
Medical Conditions Associated with Personality Change

Head trauma
Cerebrovascular diseases
Cerebral tumors
Epilepsy (particularly, complex partial epilepsy)
Huntington disease
Multiple sclerosis
Endocrine disorders

Heavy metal poisoning (manganese, mercury)
Neurosyphilis
Acquired immune deficiency syndrome (AIDS)

Electrophysiology. Changes in electrical conductance on the electroencephalogram (EEG) occur in some patients with personality disorders, most commonly antisocial and borderline types; these changes appear as slow-wave activity on EEGs.

Other Biologic Factors. In the case of personality change due to another medical condition, structural damage to the brain is usually the cause, and head trauma is probably the most common cause. Cerebral neoplasms and vascular accidents, particularly of the temporal and frontal lobes, are also common causes. The conditions most often associated with personality change are listed in Table 19-13.

Psychoanalytic Factors

Sigmund Freud suggested that personality traits are related to a fixation at one psychosexual stage of development. For example, those with an oral character are passive and dependent because they are fixated at the oral stage when the dependence on others for food is prominent. Those with an anal character are stubborn, parsimonious, and highly conscientious because of struggles over toilet training during the anal period.

Wilhelm Reich subsequently coined the term *character armor* to describe individuals' characteristic defensive styles for protecting themselves from internal impulses and interpersonal anxiety in significant relationships. Reich's theory has had a broad influence on contemporary concepts of personality and personality disorders. For example, each human being's unique stamp of personality depends on their characteristic defense mechanisms. Each personality disorder has a cluster of defenses that help psychodynamic clinicians recognize the type of character pathology present. Persons with paranoid personality disorder, for instance, use projection, whereas schizoid personality disorder is associated with withdrawal.

When defenses work effectively, persons with personality disorders master feelings of anxiety, depression, anger, shame, guilt, and other affects. Their

behavior is ego-syntonic; that is, it creates no distress for them even though it may adversely affect others. They may also be reluctant to engage in a treatment process; because their defenses are essential to controlling unpleasant affects, they are not interested in surrendering them.

In addition to characteristic defenses in personality disorders, another central feature is internal object relations. During development, a person develops particular patterns of the self in relation to others. Through introjection, children internalize a parent or another significant person as an internal presence that continues to feel like an object rather than a self. Through identification, children internalize parents and others in such a way that they incorporate the traits of the external object into the self, and the child "owns" the traits. These internal self-representations and object representations are crucial in developing the personality and, through externalization and projective identification, are played out in interpersonal scenarios in which they coerce others into playing a role in the person's internal life. Hence, persons with personality disorders are also identified by particular patterns of interpersonal relatedness that stem from these internal object relations patterns.

Defense Mechanisms. To help those with personality disorders, psychiatrists must appreciate patients' underlying defenses, the unconscious mental processes that the ego uses to resolve conflicts among the four lodestars of the inner life: instinct (wish or need), reality, important persons, and conscience. When defenses are most effective, especially in those with personality disorders, they can abolish anxiety and depression at the conscious level. Thus, abandoning a defense increases conscious awareness of anxiety and depression—a primary reason that those with personality disorders are reluctant to alter their behavior.

Although we tend to characterize patients with personality disorders by their most dominant or rigid mechanism, each patient uses several defenses. Therefore, the management of defense mechanisms used by patients with personality disorders is discussed here as a general topic and not as an aspect of the specific disorders. While many formulations are presented here in the language of psychoanalytic psychiatry, it is possible to translate them into principles consistent with cognitive and behavioral approaches.

FANTASY. Many people who are labeled schizoid—those who are eccentric, lonely, or frightened—seek solace and satisfaction within themselves by creating imaginary lives, especially imaginary friends. In their extensive dependence on fantasy, these persons often seem to be strikingly aloof. Therapists must understand that the unsociableness of these patients rests on a fear of intimacy. Rather than criticizing them or feeling rebuffed by their rejection, therapists should maintain a quiet, reassuring, and considerate interest without insisting on reciprocal responses. Recognition of patients' fear of closeness and respect for their eccentric ways are both therapeutic and useful.

DISSOCIATION. Dissociation is an unconscious defense mechanism that involves separating a mental or behavioral process (e.g., thought, feeling) from the rest of the person's psychic activity. Patients with borderline personality disorder may demonstrate dissociation during times of increased stress, including derealization or depersonalization.

ISOLATION. Isolation involves the separation of an idea or memory from its attached emotion. It is characteristic of controlled, orderly persons who are often labeled obsessive-compulsive personalities. These individuals remember the truth in fine detail but without affect. In a crisis, patients may show intensified self-restraint, overly formal social behavior, and obstinacy. Patients' quests for control may annoy clinicians or make them anxious. Often, such patients respond well to precise, systematic, and rational explanations and value efficiency, cleanliness, and punctuality as much as they do clinicians' effective responsiveness. Whenever possible, therapists should allow such patients to control their own care and should not engage in a battle of wills.

PROJECTION. In projection, patients attribute their unacknowledged feelings to others. Patients' excessive faultfinding and sensitivity to criticism may appear to therapists as prejudiced, hypervigilant, and injustice-collecting, but the therapist should not respond with defensiveness and argument. Instead, clinicians should frankly acknowledge even minor mistakes on their part and should discuss the possibility of future difficulties. Strict honesty, concern for patients' rights, and maintaining the same formal, concerning distance as

used with patients who use fantasy defenses are all helpful. Confrontation guarantees a lasting enemy and early termination of the interview. Therapists need not agree with patients' injustice-collecting, but they should ask whether both can agree to disagree.

The technique of counterprojection is especially helpful. Clinicians acknowledge and give paranoid patients full credit for their feelings and perceptions; they neither dispute patients' complaints nor reinforce them but agree that the world described by patients is conceivable. Interviewers can then talk about real motives and feelings, misattributed to someone else, and begin to cement an alliance with patients.

SPLITTING. In splitting, the patient divides persons toward whom they are, or have been, ambivalent into good and bad. For example, in an inpatient setting, a patient may idealize some staff members and uniformly disparage others. This defense behavior can be highly disruptive in a hospital ward and can ultimately provoke the staff to turn against the patient. When staff members anticipate the process, discuss it at staff meetings, and gently confront the patient with the fact that no one is all good or all bad, the phenomenon of splitting can be dealt with effectively.

ACTING OUT. In acting out, patients directly express unconscious wishes or conflicts through action to avoid being conscious of either the accompanying idea or the affect. Tantrums, apparently motiveless assaults and pleasureless promiscuity are typical examples. Because the behavior occurs outside reflective awareness, acting out appears to observers to be unaccompanied by guilt, but when acting out is impossible, the conflict behind the defense may be accessible. The clinician faced with acting out, either aggressive or sexual, in an interview situation, must recognize that the patient has lost control, that the patient will mishear anything the interviewer says, and that getting the patient's attention is of paramount importance. Depending on the circumstances, a clinician's response may be, "How can I help you if you keep screaming?" Alternatively, if the patient's loss of control seems to be escalating, say, "If you continue screaming, I will leave." An interviewer who feels genuinely frightened of the patient can simply leave and, if necessary, ask for help from ward attendants or the police.

PROJECTIVE IDENTIFICATION. The defense mechanism of projective identification appears mainly in borderline personality disorder and consists of three steps. First, the patient projects an aspect of the self onto someone else. The projector then tries to coerce the other person into identifying what they projected. Finally, the recipient of the projection and the projector feel a sense of oneness or union.

Temperament

Temperament refers to the body's biases in the modulation of conditioned behavioral responses to prescriptive physical stimuli. Behavioral conditioning (i.e., procedural learning) involves presemantic sensations that elicit basic emotions, such as fear or anger, independent of conscious recognition, descriptive observation, reflection, or reasoning. Pioneering work by A. Thomas and S. Chess conceptualized temperament as the stylistic component ("how") of behavior, as differentiated from the motivation ("why") and the content ("what") of behavior. Modern concepts of temperament emphasize its emotional, motivational, and adaptive aspects. Specifically, four major temperament traits have been identified and subjected to extensive neurobiologic, psychosocial, and clinical investigation: harm avoidance, novelty seeking, reward dependence, and persistence. These four temperaments are now understood to be genetically independent dimensions that occur in all possible combinations within the same individual rather than as mutually exclusive categories.

Psychobiology of Temperament. Temperament traits of harm avoidance, novelty seeking, reward dependence, and persistence are heritable differences underlying one's automatic response to danger, novelty, social approval, and intermittent reward, respectively. These four temperaments are closely associated with the four basic emotions of fear (harm avoidance), anger (novelty seeking), attachment (reward dependence), and ambition (persistence).

Individual differences in temperament and basic emotions modify the processing of sensory information and shape early learning characteristics, especially associative conditioning of unconscious behavior responses and preattentive components of perception. Temperament occurs in terms of

heritable biases in emotionality and learning that underlie the acquisition of emotion-based, automatic behavioral traits and habits observable early in life and relatively stable over one's lifespan.

Each of the four major dimensions is a normally distributed quantitative trait, moderately heritable, observable early in childhood, relatively stable in time, and moderately predictive of adolescent and adult behavior. The four dimensions are genetically homogeneous and independently inherited from one another, as per several extensive international twin studies. Temperamental differences, which are not very stable initially, tend to stabilize during the second and third years of life. Accordingly, ratings of these four temperament traits at ages 10 to 11 years were moderately predictive of personality traits at ages 15, 18, and 27 years in a large sample of Swedish children.

The four dimensions are universal across different cultures, ethnic groups, and political systems on every inhabited continent. We call these aspects of personality temperaments because they are heritable, manifest early in life, are developmentally stable, and are consistent in different cultures. Temperament traits are similar to crystallized intelligence in that they do not show the rapid changes with increasing age or across birth cohorts found for fluid intelligence and character traits. Table 19-14 summarizes contrasting sets of behaviors that distinguish extreme scorers on the four dimensions of temperament. Note that each extreme of these dimensions has specific adaptive advantages and disadvantages so that neither high nor low scores inherently mean better adaptation.

Each of the four temperament dimensions has unique genetic determinants according to family and twin studies, as well as studies of genetic associations with specific DNA markers.

HARM AVOIDANCE. Harm avoidance involves a heritable bias in the inhibition of behavior in response to signals of punishment and frustrative non-reward. High harm avoidance is a fear of uncertainty, social inhibition, shyness, passive avoidance of problems/danger, rapid fatigability, and pessimistic worry in anticipation of problems even in situations that do not worry others. Those low in harm avoidance are carefree, courageous, energetic, outgoing, and optimistic, even in situations that worry most people.

The psychobiology of harm avoidance is complex. Benzodiazepines

disinhibit avoidance by γ-aminobutyric acid (GABA)-ergic inhibition of serotonergic neurons originating in the dorsal raphe nuclei. The anterior serotonergic cells in the dorsal raphe nucleus intermingle with the dopaminergic cells of the ventral tegmental area, and both groups innervate the same structures (e.g., basal ganglia, accumbens, amygdala), providing opposing dopaminergic-serotonergic influences in the modulation of approach and avoidance behavior. Persons given serotonin drugs show decreased harm avoidance behavior.

Table 19-14

Descriptors of Individuals Who Score High or Low on the Four Temperament Dimensions

Temperament Dimension	Descriptors of Extreme Variants	
	High	Low
Harm avoidance	Pessimistic	Optimistic
	Fearful	Daring
	Shy	Outgoing
	Fatigable	Energetic
Novelty seeking	Exploratory	Reserved
	Impulsive	Deliberate
	Extravagant	Thrifty
	Disorderly	Orderly
Reward dependence	Sentimental	Detached
	Open	Aloof
	Warm	Cold
	Affectionate	Independent
Persistence	Industrious	Lazy

	Determined	Spoiled
	Ambitious	Underachiever
	Perfectionist	Pragmatist

NOVELTY SEEKING. Novelty seeking reflects a heritable bias in the initiation or activation of appetitive approach in response to novelty, approach to signals of reward, active avoidance of conditioned signals of punishment, and escape from unconditioned punishment. Novelty seeking is an exploratory activity in response to novelty, impulsiveness, extravagance in approach to cues of reward, and active avoidance of frustration. Individuals high in novelty seeking are quick-tempered, curious, easily bored, impulsive, extravagant, and disorderly. Those low in novelty seeking are slow tempered, uninquiring, stoical, reflective, frugal, reserved, tolerant of monotony, and orderly.

Dopaminergic projections have a crucial role in novelty seeking. Novelty seeking seems to involve increased reuptake of dopamine at presynaptic terminals, thereby requiring frequent stimulation to maintain optimal levels of postsynaptic dopaminergic stimulation. Studies of candidate genes involved in dopamine neurotransmission, have provided evidence of association with novelty seeking and no other dimension of temperament.

REWARD DEPENDENCE. Reward dependence reflects the maintenance of behavior in response to cues of social reward. Individuals high in reward dependence are tender-hearted, sensitive, dedicated, dependent, and warmly sociable. Those low in reward dependence are practical, tough-minded, cold, socially insensitive, irresolute, and indifferent if alone.

Noradrenergic projections from the locus coeruleus and serotonergic projections from the median raphe likely influence such reward conditioning. The "love hormone" oxytocin's plasma level is positively correlated ($r = 0.5$) with individual differences in reward dependence but not other dimensions of personality.

PERSISTENCE. Persistence reflects the maintenance of behavior despite frustration, fatigue, and intermittent reinforcement. It manifests as industriousness, determination, ambitiousness, and perfectionism. Highly persistent individuals are hard-working, perseverant, and ambitious

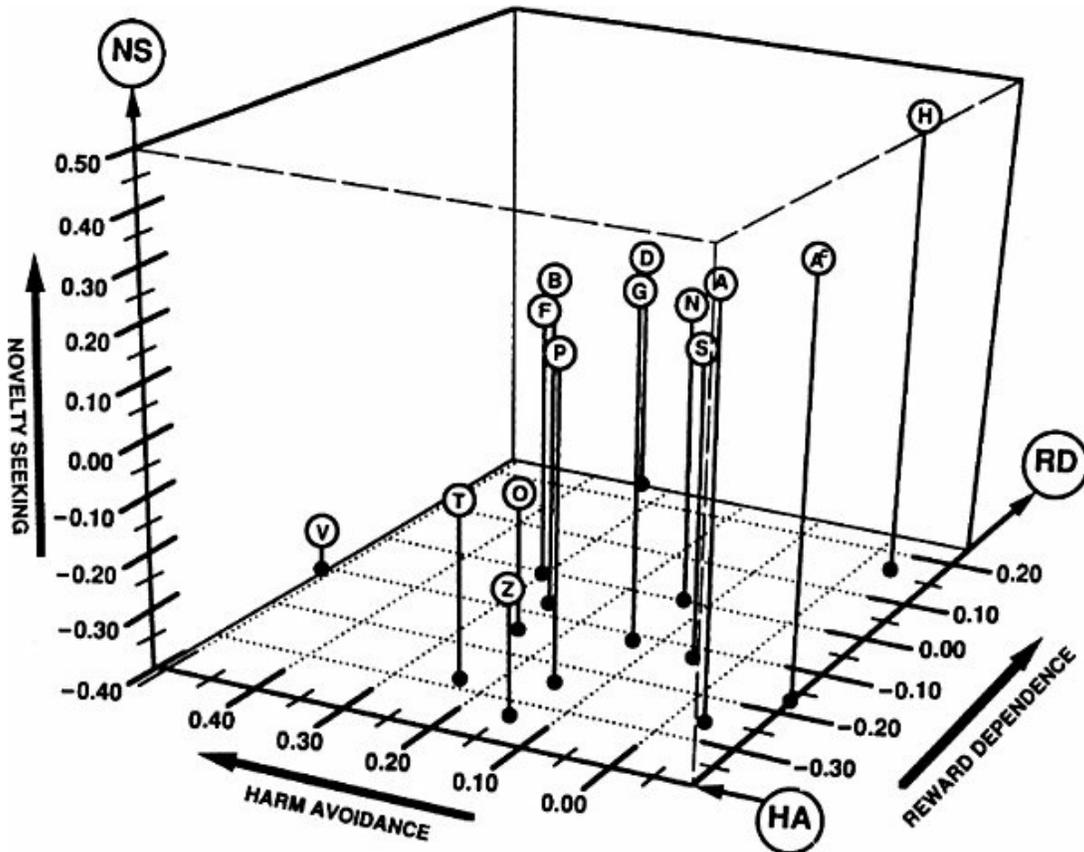
overachievers who tend to intensify their effort in response to anticipated rewards and view frustration and fatigue as personal challenges. Those low in persistence are indolent, inactive, unstable, and erratic; they tend to give up easily when faced with frustration, rarely strive for higher accomplishments, and manifest little perseverance even in response to intermittent reward.


FIGURE 19-1
Correlations between individual personality disorder subtypes and temperament traits of harm avoidance (HA), novelty seeking (NS), and reward dependence (RD). A, antisocial; Ac, antisocial children; B, borderline; D, dependent; F, self-defeating; G, passive aggressive; H, histrionic; N, narcissistic; O, obsessive; P, paranoid; S, sadistic; GT, schizotypal; V, avoidant; Z, schizoid.

Individual differences in persistence have been strongly correlated ($r = 0.8$) with responses measured by fMRI in a circuit involving the ventral striatum, orbitofrontal cortex/rostral insula, and dorsal anterior cingulate cortex.

Figure 19-1 illustrates the interrelationships between the personality disorders and the temperament traits of harm avoidance, novelty seeking, and reward dependence.

Other Conditions that May be a Focus of Clinical Attention

INTRODUCTION

DSM-5 includes a section called Other Conditions that May be a Focus of Clinical Attention. ICD-10 has a similar section called Factors Influencing Health Status and Contact with Health Services. These sections are for conditions that are not mental disorders but that have led to contact with the mental health care system. In some instances, one of these conditions will be noted during a psychiatric evaluation (e.g., divorce), although there is no mental disorder. In other instances, the diagnostic evaluation reveals no mental disorder, but there is a need to note the primary reason for contact with the mental health care system (e.g., homelessness).

In some cases, we may eventually find a mental disorder, but the focus of attention or treatment is on a condition that is not caused by a mental disorder. For example, a patient with an anxiety disorder may receive treatment for a marital problem that is unrelated to the anxiety disorder itself.

Table 20-1 includes the many conditions DSM-5 lists that may be a focus of clinical attention, or that may influence the diagnosis, treatment, or course of a mental disorder contained in DSM-5. The list of conditions that make up this category covers the entire life cycle from infancy through childhood, adolescence, adulthood, and old age. The list of conditions covers almost every conceivable life circumstance, from divorce to problems related to being in military service. Each of these conditions or circumstances is capable of having a profound input on a particular mental illness or the human experience in general.

MALINGERING

Malingering is the deliberate falsification of physical or psychological symptoms in an attempt to achieve a secondary gain such as avoiding military duty, avoiding work, obtaining financial compensation, evading criminal prosecution, or obtaining drugs. Under some circumstances, malingering may represent adaptive behavior—for example, as mentioned below, feigning illness while a captive of the enemy during wartime.

The clinician should consider possible malingering when encountering any combination of the following: (1) medicolegal context of presentation (e.g., the person is referred by an attorney to the clinician for examination), (2) evident discrepancy between the individual's claimed stress or disability and the objective findings, (3) lack of cooperation during the diagnostic evaluation and in complying with the prescribed treatment regimen, and (4) the presence of antisocial personality disorder.

Diagnosis and Clinical Features

Avoidance of Criminal Responsibility, Trial, and Punishment. Criminals may pretend to be incompetent to avoid standing trial; they may feign insanity at the time of the perpetration of the crime, malinger symptoms to receive a less harsh penalty, or attempt to act too incapacitated (incompetent) for punishment.

Avoidance of Military Service or Particularly Hazardous Duties. Persons may malinger to avoid conscription into the armed forces, and, after being conscripted, they may feign illness to escape from particularly onerous or hazardous duties.

Financial Gain. Malingerers may seek financial gain in the form of undeserved disability insurance, veterans' benefits, workers' compensation, or tort damages for purported psychological injury.

Avoidance of Work, Social Responsibility, and Social Consequences. Individuals may malinger to escape from unpleasant vocational or social circumstances or to avoid the social and litigation-related

consequences of vocational or social improprieties.

An owner of a previously successful photographic equipment supplier declared bankruptcy in a way that the government maintained was illegal. Subsequently, the government indicted the defendant on various counts of fraud. The defendant's counsel maintained that the defendant was too depressed to cooperate with him and that, because of that depression, he experienced memory loss that made it impossible to understand what had occurred and, therefore, impossible to provide a meaningful defense. The government's forensic psychiatrist evaluated the defendant to ascertain the nature of his depression and to determine whether it was causing cognitive problems.

When asked early in his evaluation when his birthday was, he responded, "Oh, what does it matter? It was in the 40s or 50s." Similarly, when queried about where he was born, he said, "Somewhere in Hungary." Even when pressed for more specifics, he refused to elaborate. Nevertheless, at many points later in his evaluation, he responded with complete, often detailed information about transactions not related to those for which he was under indictment. It was the impression of the evaluator that the defendant was malingering grossly and inconsistently, incompatible with the kinds of decreases in cognitive skills that occasionally attend major depression. (Adapted from a case of Mark J. Mills, J.D., M.D. and Mark S. Lipian, M.D., Ph.D.)

Table 20-1
Conditions that May be a Focus of Clinical Attention

Relational Problems
- Problems Related to Family Upbringing
  - Parent–Child Problem
  - Sibling Problem
  - Upbringing Away from Parents
  - Parental Relationship Distress
- Other Problems Related to Primary Support System

- Relationship Distress with Spouse or Partner
- Separation or Divorce
- Emotional Distress within Family
- Uncomplicated Bereavement

Abuse and Neglect
- Problems of Child Maltreatment and Neglect
  - Child Physical Abuse
  - Child Sexual Abuse
  - Child Neglect
  - Child Psychological Abuse
- Problems of Adult Maltreatment and Neglect
  - Physical Violence of Spouse or Partner
  - Sexual Violence of Spouse or Partner
  - Spouse or Partner Neglect
  - Psychological Spouse or Partner Abuse
  - Adult Abuse by Nonspouse or Nonpartner (e.g., Physical, Sexual, Psychological)

Educational and Occupational Problems
- Educational Problems
- Occupational Problems
  - Related to Current Military Deployment Status
  - Other (e.g., Job change, Loss of job, Stress)

Housing and Economic Problems
- Housing Problems
  - Homelessness
  - Inadequate Housing (e.g., Lack of Heat or Electricity, Insect or Rodent Infestation)
  - Neighbor, Lodger, or Landlord Discord
  - Residential Institution (Does Not Include Psychological Reaction to Change in Living Situation; see Adjustment Disorders, Chapter 10)
- Economic Problems
  - Lack of Adequate Food or Safe Drinking Water

- Extreme Poverty
- Low Income

Other Problems Related to the Social Environment
- Phase of Life Problem
- Acculturation Difficulty
- Social Exclusion or Rejection
- Discrimination or Persecution

Problems Related to Crime or Interaction with the Legal System (e.g., Victim of Crime, Imprisonment, Release from Prison)

Other Health Service Encounters for Counseling and Medical Advice (e.g., Sexual Counseling)

Problems Related to Other Psychological, Personal, and Environmental Circumstances
- Religious or Spiritual Problem
- Victim of Terrorism or Torture
- Exposure to Disaster or War

Other Circumstances of Personal History
- Adult Antisocial Behavior
- Child or Adolescent Antisocial Behavior
- Problems Related to Access to Medical and Other Health Care
- Nonadherence to Medical Treatment (e.g., Overweight or Obesity, Malingering, Wandering Associated with a Mental Disorder)
- Borderline Intellectual Functioning

Adapted from *Diagnostic and Statistical Manual of Mental Disorders*. 5th ed., American Psychiatric Association; 2013.

Facilitation of Transfer from Prison to Hospital. Prisoners may malinger (fake bad) to obtain a transfer to a psychiatric hospital from which they may hope to escape or in which they expect to do "easier time." The prison context may also give rise to dissimulation (faking good). However, the prospect of an indeterminate number of days on a mental health ward may prompt an inmate with actual psychiatric symptoms to make every effort to

conceal them.

Admission to a Hospital. In this era of deinstitutionalization and homelessness, individuals may malinger to gain admission to a psychiatric hospital. The individual may see such institutions as providing free room and board, a haven from the police, or refuge from rival gang members or disgruntled drug cronies who have made street life even more unbearable and hazardous than it usually is.

A robust, neatly attired man presented to the psychiatric emergency department in the early-morning hours. He stated that "the voices" were worse than before and that he wished readmission to the hospital. When the psychiatrist challenged him, observing that his discharge was just that afternoon, that he routinely left the hospital in the morning and demanded rehospitalization at night, and that, despite multiple hospitalizations, clinicians increasingly doubted his reported history of hallucinations, the man became belligerent. When the psychiatrist still refused to admit him, the patient grabbed the psychiatrist's clothes, threatening him but inflicting no harm. The psychiatrist asked the hospital police to escort him off the grounds. The treatment team told the patient that he could seek readmission to his regular ward during the day. Subsequent contact with the patient's ward revealed that their diagnoses were substance abuse and homelessness; his apparent schizophrenia appeared never to have been an actual issue in his treatment. (Courtesy of Mark J. Mills, J.D., M.D. and Mark S. Lipian, M.D., Ph.D.)

Drug Seeking. Malingerers may feign illness to obtain favored medications, either for personal use or, in a prison setting, as currency to barter for cigarettes, protection, or other inmate-provided favors.

The plaintiff, a woman in her late 20s, was injured while dancing at a club. Although her claim initially appeared bona fide, subsequent investigation cast doubt on the mechanism of injury that she claimed— namely, that a misplaced electrical cord under a carpet caused her to slip.

This was true, she claimed, even though she had been dancing in a particularly jerky manner that could have easily caused problems without tripping.

Subsequently, she sought medical and surgical treatment for torn cartilage in her injured knee. Even though the initial surgery went well, she kept reinjuring the knee with various "slips." As a result, she requested narcotic analgesics. A careful medical record review revealed that she was obtaining such medications from multiple practitioners and that she had forged at least one prescription.

In reviewing the case before binding arbitration, it was the opinion of the orthopedic and psychiatric consultants that, although the initial injury and reported pain were real, the plaintiff consciously elaborated her injuries to obtain the desired narcotic analgesics. (Courtesy of Mark J. Mills, J.D., M.D. and Mark S. Lipian, M.D., Ph.D.)

Child Custody. Minimizing difficulties or faking good for the sake of obtaining child custody can occur when one party accurately accuses the other of being an unfit parent because of psychological conditions. The accused party may feel compelled to minimize symptoms or to portray him- or herself in a positive light to reduce the chances of being deemed unfit and losing custody.

Differential Diagnosis

The challenge is to differentiate malingering from an actual physical or psychiatric illness. Furthermore, the possibility of partial malingering, which is an exaggeration of existing symptoms, must be entertained. Also, the possibility exists of unintentional, dynamically driven misattribution of genuine symptoms (e.g., of depression) to an incorrect environmental cause (e.g., to sexual harassment rather than to narcissistic injury).

We should also remember that a real psychiatric disorder and malingering are not mutually exclusive.

Factitious disorder is distinguished from malingering by motivation (sick role vs. tangible pain), whereas the somatoform disorders involve no conscious volition. In conversion disorder, as in malingering, objective signs cannot account for subjective experience, and differentiation between the two

disorders can be difficult. Table 20-2 lists some variables that may aid in distinguishing between these two conditions.

Epidemiology

There is perhaps a 1 percent prevalence of malingering among mental health patients in civilian clinical practice, with the estimate rising to 5 percent in the military. In a litigious context, during interviews of criminal defendants, the estimated prevalence of malingering is much higher—between 10 and 20 percent. Approximately 50 percent of children presenting with conduct disorders have reported lying-related issues.

Although there is no apparent familial or genetic patterns, and no clear-cut sex or age bias at onset, malingering does appear to be highly prevalent in some military, prison, and litigious populations and, in Western society, in men from youth through middle age. Associated disorders include conduct and anxiety disorders in children and antisocial, borderline, and narcissistic personality disorders in adults.

Etiology

Although there do not seem to be any biologic factors causally related to malingering, its frequent association with antisocial personality disorder raises the possibility that hypoarousability may be an underlying metabolic factor. Still, no predisposing genetic, neurophysiologic, neurochemical, or neuroendocrinologic forces are presently known.

Table 20-2
Factors Aiding in the Differentiation between Malingering and Conversion Disorder

1. Malingerers are more likely to be suspicious, uncooperative, aloof, and unfriendly; patients with conversion disorder are likely to be friendly, cooperative, appealing, dependent, and clinging.
2. Malingerers may try to avoid diagnostic evaluations and refuse recommended treatment; patients with conversion disorder likely welcome evaluation and treatment, "searching for an answer."
3. Malingerers likely refuse employment opportunities designed to

circumvent their disability; patients with conversion disorder likely accept such opportunities.
4. Malingerers are more likely to provide extremely detailed and exacting descriptions of events precipitating their "illness"; patients with conversion disorder are more likely to report historical gaps, inaccuracies, and vagaries.

Course and Prognosis

Malingering persists as long as the malingerer believes it will likely produce the desired rewards. In the absence of concurrent diagnoses, after the individual has attained the goal, the feigned symptoms disappear. In some structured settings, such as the military or prison units, ignoring the malingered behavior may result in its disappearance, mainly if an expectation of continued productive performance, despite complaints, is made clear. In children, malingering is most likely associated with a predisposing anxiety or conduct disorder; proper attention to this developing problem may alleviate the child's propensity to malinger.

Treatment

The appropriate stance for the psychiatrist is clinical neutrality. If malingering is suspected, a careful differential investigation should ensue. If, after the diagnostic evaluation, malingering seems most likely, the clinician should tactfully but firmly confront the patient with the apparent outcome. The clinician should also try to understand the underlying reasons for the ruse, and explore alternative, more acceptable pathways to the desired outcome. Coexisting psychiatric disorders should be thoroughly assessed. Only if the patient is utterly unwilling to interact with the physician under any terms other than manipulation should the physician abandon the interaction.

BEREAVEMENT

Normal bereavement begins immediately after or within a few months of the loss of a loved one. Typical signs and symptoms include feelings of sadness, preoccupation with thoughts about the deceased, tearfulness, irritability,

insomnia, and difficulties concentrating and carrying out daily activities. Based on the cultural group, bereavement is limited to a varying time, usually 6 months, but it can be longer. Normal bereavement, however, can lead to a full depressive disorder that requires treatment. Some grieving individuals present with symptoms characteristic of a major depressive episode such as depressed mood, insomnia, anorexia, and weight loss. The duration of grief and bereavement varies considerably among different cultural groups and within the same cultural group. The diagnosis of depressive disorder is generally not given unless the symptoms are still present 2 months after the loss. However, the presence of specific symptoms that are not characteristic of a "normal" grief reaction may help differentiate bereavement from depression. These include (1) guilt about things other than actions taken or not taken by the survivor at the time of the death, (2) thoughts of death other than the survivor feeling that he or she would be better off dead or should have died with the deceased person, (3) morbid preoccupation with worthlessness, (4) marked psychomotor retardation, (5) prolonged and marked functional impairment, and (6) hallucinatory experiences other than thinking that he or she hears the voice of or transiently sees the image of the deceased person.

OCCUPATIONAL PROBLEMS

Occupational problems often arise during stressful changes in work, namely, at initial entry into the workforce or when making job changes within the same organization to a higher position because of excellent quality performance or to a parallel position because of corporate need. Distress often occurs when not choosing these changes or if the person feels unprepared for the change. It is also true during layoffs and at retirement, especially if retirement is mandatory, and the person is unprepared for this event. Work distress can result if one's work situation changes to work overload, or conversely, a lack of challenge. Also, an individual may feel unable to fulfill work expectations, perhaps because they lack sufficient authority to enact any change or meet with conflicting expectations. Working with harsh or unreasonable superiors can be another common source of work distress.

Work Choices and Changes

Young adults without role models or guidance from families, mentors, or others in their communities too often underestimate their potential lifetime abilities to learn a trade or earn a college or postgraduate degree. Also, women and members of minority groups often feel less prepared to accept work challenges, fear rejection, and do not apply for jobs for which they are qualified. On the other hand, men, in fields in which they are underrepresented, often and confidently move up the career ladder faster (glass elevator). As part of initial interviews for evaluation of occupational problems, patients should be encouraged to consider their heretofore unrecognized, unadmitted talents; long-held, yet unexpressed, dreams and goals regarding work; actual successes in work and school; and motivation to risk learning what they would find satisfying.

Minorities and those in low-paying and low-skilled jobs too often have less job security. Business and institutional reorganization and consequent downsizing, factory closings, and moves affect many, often leaving these workers feeling hopeless and helpless about future employment, on welfare, angry, and depressed.

With ongoing and often sudden downsizing of corporations and businesses, men and women continue to struggle with unexpected job loss and premature retirement even when finances are not an issue. Also, men, in particular, define themselves by their work roles and thus experience more occupational distress from these changes. Women may adjust faster to retirement, but they often have less financial security than men. Even today, white women earn approximately 80 cents on the dollar, and African American and Hispanic women earn even less for comparable work. In addition to lower pay, women may have lower status, find themselves widowed more often than men, and are more likely to be caring for children, grandchildren, and elderly relatives. Women represent more of the single working parent group and the working poor.

Stress and the Workplace

More than 30 percent of workers report that they are under stress at work. At least 15 percent of occupational disability claims involve workplace distress. Expected distress follows recognized and uncontrollable work changes—

downsizing, mergers and acquisitions; work overload; and chronic physical strains, including work noise, temperature, bodily injuries, and strain from performing computer work.

Work frustration can also arise from an individual worker's unrecognized (and therefore unresolved) psychodynamic issues, such as working appropriately with superiors and not relating to one's supervisor as a parent figure. Other developmental issues include unresolved problems with competition, assertiveness, envy, fear of success, and the inability to communicate verbally in a constructive manner.

After the September 11, 2001, World Trade Center tragedy, a 32-year-old married male firefighter, who had been away on vacation that day with his wife and children, began to exhibit changed behaviors at home and work. At home, he appeared not to listen to his two children and, instead, focused his attention on television sporting events. At work, he also appeared to be more focused on cooking the same dinners for his peers and watching television than on interacting verbally with his remaining peers and the new chief. In several months, a chaplain visited the station several times and talked to the firefighters about survivor guilt and the 9/11 tragedy, and the firefighter began to return somewhat to his former healthier behaviors. (Courtesy of Leah J. Dickstein, M.D.)

Often, work conflicts reflect similar conflicts in the worker's personal life, and referral for treatment, unless there is insight, is in order. Some studies have found that massage therapy, meditation, and yoga at intervals during the workday relieve stress when used regularly. Approaches using cognitive therapy have also helped people reduce work pressure.

Suicide Risk

Some occupations—health professionals, financial service workers, and police, the first and latter groups because of more access to lethal drugs and weapons—both attract persons with high suicide risk and involve increased chronic distress that may lead to higher suicide rates.

Career and Job Problems of Women

Most women work outside the home out of necessity to support themselves or their dependents (whether children or adults) or as part of a working couple. With the divorce rate remaining at the 50 percent level, many women find themselves economically more impoverished after a divorce than when married, although divorced men usually find their economic status improved. Despite more than four decades of increasing knowledge about and concern for women's status in the workplace, unique gender issues, bias, and lack of accommodation to their unique needs at certain life stages (i.e., pregnancy and postpartum, the primary responsibility for young healthy and ill children) continue. However, women were the largest group establishing new small businesses in the 1990s. Many have left large corporations where they felt undervalued because of their gender. Women experience problems when they are the sole woman in a man's field. Despite increasing recognition of the need for men in relationships with women to assume home and family responsibilities, fewer than 25 percent of men do so equitably.

Women of childbearing and child-rearing ages continue to find themselves in conflict with job expectations, opportunities, and personal responsibilities. High-quality, on-site, dependent-care facilities with extended hours are rare and often out of range financially. Major unresolved work issues that are unique to women at certain life stages include flextime and paid and unpaid dependent leave options. Beyond dependent care issues, women in the workforce continue to experience distress after chronic and repeated sexual harassment, despite its illegality and media attention. Increasingly, more women have travel responsibilities, work long hours, work shifts beyond daylight hours, and experience personal workplace violence.

Among dual-career families and partners, the woman is more likely to move when the man chooses to move for a work opportunity than vice versa. Consequently, a woman's career is interrupted more often. There is now less hesitation to have the two members of a relationship work for the same organization than previously, albeit usually in different departments. Work distress may also stem from continuous miscommunication, especially that based on gender.

Working Teenagers

With unemployment increasing, many teenagers work part time while attending high school. Consequently, stress can arise because of less parent–teenager interaction and constructive parental control issues about teens' use of earnings, time spent away from home, and consequent behaviors both in and outside the home. When both parents or a single parent, as well as the teenager, work outside the home, often on different schedules, parent–teen verbal communication must be proactive, transparent, and ongoing.

Working within the Home

Although most women with children of all ages must work outside the home, at times, they may be home full time or part time or may work at home. When their husbands or partners work full time outside the home, problems may develop from each one's perceived expectations of the other. Women who care for children and their home exclusively may be seen by their partners as not only economically dependent and inferior but also not as competent and not understanding of the man's stressors and needs. Ongoing respectful listening and verbal communication must be encouraged.

People in organizations are increasingly taking work home as their work expectations increase. This work-at-home experience can and does interfere with personal lives and satisfaction, which can then have further repercussions at work.

Chronic Illness

As general and other medical and psychiatric treatments for chronic diseases improve, employers have been increasingly concerned about accommodating patients with acquired immunodeficiency syndrome (AIDS), diabetes mellitus, and other disorders. The issue of mandatory testing for AIDS and substance abuse (alcohol and other illegal substances) continues to be of concern. Employee assistance programs offering education about general and mental health topics have proved timely and cost-effective.

Domestic Violence

Although occurring in the home, signs and symptoms that interfere with work may help identify victims of domestic violence. Trained professionals must question all employees experiencing work distress about domestic violence

and, when indicated, refer individuals for assistance, which includes safety in the workplace.

Job Loss

Regardless of the reason for job loss, most people experience distress, at least temporarily, including symptoms of normal grief, loss of self-esteem, anger, and reactive depressive and anxiety symptoms, as well as somatic symptoms and possibly the onset of or increase in substance abuse or domestic violence. Timely education, support programs, and vocational guidance can be helpful, as is access to treatment.

Vocational Rehabilitation

Rehabilitation is often necessary for those traumatized by stresses in the workplace, those who had to take a leave for medical or psychiatric reasons, and those who lose their jobs. Individual or group counseling enables persons to improve personal relationships, raise self-esteem, or learn new work skills. Patients with schizophrenia may benefit from sheltered workshops in which they perform work geared to their level of function. Some patients with schizophrenia or autism do well in tasks that are repetitive or require obsessive concern with details.

ADULT ANTISOCIAL BEHAVIOR

Characterized by activities that are illegal, immoral, or both, antisocial behavior usually begins in childhood and often persists throughout life. The term *antisocial behavior* somewhat confusingly applies both to persons' actions that are not due to a mental disorder and to actions by those who never received a neuropsychiatric workup to determine the presence or absence of a mental disorder. As Dorothy Lewis noted, the term can apply to behavior by otherwise normal persons who "struggle to make a dishonest living."

Diagnosis and Clinical Features

The diagnosis of adult antisocial behavior is one of exclusion. Substance dependence in such behavior often makes it difficult to separate the antisocial

behavior related primarily to substance dependence from disordered behaviors that occurred either before substance use or during episodes unrelated to substance dependence.

It is also essential that we differentiate this from an antisocial personality disorder, and when a patient meets the criteria for the personality disorder, that diagnosis would supersede this one.

During the manic phases of bipolar I disorder, certain aspects of behavior, such as wanderlust, sexual promiscuity, and financial difficulties can be similar to adult antisocial behavior. Patients with schizophrenia may have episodes of adult antisocial behavior, but the symptom picture is usually clear, especially regarding thought disorder, delusions, and hallucinations on the mental status examination.

Neurologic conditions can be associated with adult antisocial behavior, and, when indicated, a full workup, including neuroimaging, can help identify a cause of the behavior. We should consider complex partial seizures in the differential diagnosis. When making a clear-cut diagnosis of epilepsy or encephalitis, we should then consider whether the disorder is contributing to antisocial behavior. Abnormal EEG findings are prevalent among violent offenders: an estimated 50 percent of aggressive criminals have abnormal EEG findings.

Persons with adult antisocial behavior have difficulties in work, marriage, and money matters and conflicts with various authorities. Table 20-3 summarizes the symptoms of adult antisocial behavior.

Epidemiology

Depending on the specifics of the case finding, adult antisocial behavior may range from 5 to 15 percent of the population. Within prison populations, investigators report prevalence figures between 20 and 80 percent. Men account for more adult antisocial behavior than do women.

Table 20-3
Symptoms of Adult Antisocial Behavior

Life Area	Antisocial Patients with Significant Problems in Area (%)

Work problems	85
Marital problems	81
Financial dependence	79
Arrests	75
Alcohol abuse	72
School problems	71
Impulsiveness	67
Sexual behavior	64
Wild adolescence	62
Vagrancy	60
Belligerence	58
Social isolation	56
Military record (of those serving)	53
Lack of guilt	40
Somatic complaints	31
Use of aliases	29
Pathologic lying	16
Drug abuse	15
Suicide attempts	11

Data from Robins L. *Deviant Children Grown Up: A Sociological and Psychiatric Study of Sociopathic Personality*. Baltimore, MD: Williams & Wilkins; 1966.

Etiology

Antisocial behaviors in adulthood are characteristic of a variety of persons, ranging from those with no demonstrable psychopathology to those who are

severely impaired and have psychotic disorders, cognitive disorders, and retardation, among other conditions. A comprehensive neuropsychiatric assessment of antisocial adults is indicated and may reveal potentially treatable psychiatric and neurologic impairments. Only in the absence of mental disorders can patients be categorized as displaying adult antisocial behavior. Genetic and social factors may influence adult antisocial behavior.

Genetic Factors. Some studies found a 60 percent concordance rate in monozygotic twins and about a 30 percent concordance rate in dizygotic twins. Adoption studies show a high rate of antisocial behavior in the biologic relatives of adoptees identified with antisocial behavior and a high incidence of antisocial behavior in the adopted-away offspring of those with antisocial behavior. The prenatal and perinatal periods of those who subsequently display antisocial behavior often are associated with low birth weight, mental retardation, and prenatal exposure to alcohol and other drugs of abuse.

Social Factors. Studies have shown that in neighborhoods in which families with low socioeconomic status (SES) predominate, the sons of unskilled workers are more likely to commit more offenses and more serious criminal offenses than do the sons of middle-class and skilled workers, at least during adolescence and early adulthood. These data are not as precise for women, but the findings are generally similar in studies from many countries. Areas of family training differ by SES group. Middle-SES parents use love-oriented techniques in discipline. They withdraw affection rather than impose physical punishment, as is done in low-SES groups. Negative parental attitudes toward aggressive behavior attempt to curb that behavior, and the ability to communicate parental values are more characteristic of middle- and high-SES groups than of low ones. Adult antisocial behavior is associated with the use and abuse of alcohol and other substances and with the easy availability of handguns.

Treatment

In general, therapists are pessimistic about treating adult antisocial behavior. They have little hope of changing a pattern that has been present almost continuously throughout a person's life. Psychotherapy has not been

effective, and no breakthroughs with biologic treatments, including medications, have occurred.

Therapists show more enthusiasm for the use of therapeutic communities and other forms of group treatment, although the data provide little basis for optimism. Many adult criminals, incarcerated in institutional settings, have shown some response to group therapy approaches. The history of violence, criminality, and antisocial behavior has shown that such behaviors seem to decrease after age 40 years. Recidivism in criminals, which can reach 90 percent in some studies, also decreases in middle age.

Prevention. Because antisocial behavior often begins during childhood, the primary focus must be on delinquency prevention. Any measures that improve the physical and mental health of socioeconomically disadvantaged children and their families are likely to reduce delinquency and violent crime. Often, recurrently violent persons have sustained many insults to the central nervous system (CNS) prenatally and throughout childhood and adolescence. Consequently, we need to develop programs to educate parents about the dangers to their children of CNS injury from maltreatment, including the effects of psychoactive substances on the brains of growing fetuses. Public education about the releasing effect of alcohol on violent behaviors (as well as its contribution to vehicular homicide) may also reduce crime.

In a Surgeon General's Workshop on Violence and Public Health (1985), the work group on preventing assault and homicide emphasized the importance of discouraging corporal punishment in the home, forbidding it in the schools, and even abolishing capital punishment by the state, saying that all are models and sanctions for violence. No evidence indicates that capital punishment reduces crime in the states that have it. Opponents of capital punishment see it as "vengeance," not punishment.

Although persons disagree about the contribution of violence in the media to violent crime, the propaganda potential of the media is universally recognized. We have not fully realized the extent to which the media, such as television, can be used to transmit positive social values. The guidelines issued by the television industry to indicate the amount of sex and violence in programs is an attempt to deal with the issue; however, program content that espouses traditional societal values would be beneficial.

The most successful preventive measures within the field of medicine have

come from community-wide public health programs (e.g., campaigns against smoking) and from programs that detect individual vulnerabilities (e.g., individual monitoring of blood pressure). Studies of adult antisocial behavior reveal the contribution of broad cultural factors and constellations of individual biopsychosocial vulnerabilities. Prevention programs must recognize and address both kinds of factors.

RELIGIOUS OR SPIRITUAL PROBLEM

A religious or spiritual problem can bring the person to the psychiatrist under one of several circumstances. For example, a person may begin to question his or her faith and choose not to discuss the problem with a spiritual advisor. Alternatively, a person may wish to convert to a new faith, to marry or improve a marriage when the partner is of a different faith.

  Psychiatrists must enable and assist patients in distinguishing religious thought or experience from psychopathology and, if this is a problem, encourage patients to work through the issues independently or with assistance. Religious imagery may be recognized in mental illness when persons state they believe that they have been commanded by God to take a dangerous or grandiose action.

Religious experiences may factor into a person's life in unexpected ways, as in the following case. A midcareer male surgeon who was very successful but long overcommitted to his private practice and his academic responsibilities revealed to his often-neglected wife that, at age 9 years, he was approached by his religious leader to get close physically and ultimately engaged in sexual acts over several years. Believing it was his fault, he never told anyone and decided never to have children. After telling his wife about the experience, they engaged in family therapy to work through the stresses the confession produced in their marriage.

Cults

Recently, cults have appeared to be less popular and less attractive to naïve late adolescents and young adults seeking assistance in discovering who they are as they struggle to develop more mature relationships with their parents.

Cults are led by charismatic leaders, often out of control themselves, with inappropriate and often unethical values but purporting to offer acceptance and guidance to troubled followers. Cult members are actively controlled and forced to dissolve allegiance to family and others to serve the cult leader's directives and personal needs. These young members often come from educated families who then seek professional help in persuading their children to leave the cult and enter deprogramming therapy to restore psychological stability to the former cult members. Deprogramming and adjustment back into the family, society, and an independent life are time-intensive and long term with resultant posttraumatic stress disorder (PTSD), which must be recognized and treated.

ACCULTURATION PROBLEM

Acculturation is the process whereby a person from one culture changes in their manner, custom, and dress to adapt to a different culture. It leads to assimilation in which the person has identified with the new culture, usually without conflict or ambivalence. In some cases, however, significant cultural change can evoke severe distress, termed *culture shock.* This condition arises when individuals suddenly find themselves in a new culture in which they feel entirely alien. They may also feel conflict over which lifestyles to maintain, change, or adopt. Children and young adult immigrants often adapt more quickly than do middle-aged and elderly immigrants. Younger immigrants often learn the new language more efficiently and continue to mature in the new culture, but those who are more senior, having had more stability and unchanging routines in their former culture, struggle more to adapt. Culture shock from immigration differs from the restless and continuous moving of psychiatric patients secondary to their illness.

Culture shock can occur within a person's own country with geographic, school, and work changes, such as joining the military, experiencing school busing, moving across the country, or moving to a vastly different neighborhood or from a rural area to a metropolis. Reactive symptoms, which are understandable, include anxiety, depression, isolation, fear, and a sense of loss of identity as the person adjusts. If the person is part of a family or group making this transition and the move is positive and planned, stress can be lower. Furthermore, if one can maintain selected cultural mores safely as they

integrate into the new culture, it may be less stressful.

Constant geographic moves because of chosen work opportunities or necessity involve a large proportion of workers in the United States. Joining activities in the new community and actively trying to meet neighbors and coworkers can lessen the culture shock.

An 18-year-old, first-year female college student offered an academic scholarship by a small Southern college with a major in her field of interest, realized on her return home to the Midwest for winter break that she felt like a misfit among her dorm peers. They were friendly yet generally kept their distance from her after class. At home, she discussed her experiences with high school friends, who replied that they had heard about such cultural dissonance from peers at their Midwestern colleges. The student returned to college feeling that it was not her fault or imagination and slowly began to reach out more assertively to her peers so they could get to know her beyond stereotypical beliefs and so she could do the same.

Brainwashing

First practiced by the Chinese Communists on American prisoners during the Korean War, *brainwashing* is the deliberate creation of culture shock. Individuals are isolated, intimidated, and made to feel different and out of place to break their spirits and destroy their coping skills. When a person appears mentally weak and helpless, the aggressors impose new ideas on them that they would never have accepted in their normal state. As with those involved in cults, on release and return to their homes, brainwashed individuals with PTSD require deprogramming treatment, including re-education and ongoing supportive psychotherapy, both on an individual and group basis. Treatment is usually long-term to rebuild healthy self-esteem and coping skills.

Prisoners of War and Torture Victims

Prisoners who survive war or torture experiences do so because of personal inner strengths developed in their earlier lives, beginning within their

emotionally healthy and caring families; if they come from troubled families, they are more likely to commit suicide during imprisonment and torture. Prisoners must continuously cope with ongoing anxiety, fear, isolation from known lives, and complete loss of all control over their lives. Those who appear to cope best believe they must survive for a reason (e.g., to tell others what they experienced or to find and return to loved ones). Prisoners who cope best describe living simultaneously on two levels—coping in the here and now to survive the situation while maintaining constant mental connections to their past values and experiences and those important to them.

Beyond the surviving prisoner's personal difficulties, including PTSD, if and when his or her survival behavior continues, his or her family may be affected by the surviving prisoner's inordinate fear of police and strangers, overprotection and overburdening of children to replace those significant others lost, lack of sharing of the past, continued isolation from current communities, or inappropriately expressed anger. Thus, another generation (i.e., children of survivors) can be affected in their personal development and psychological functioning and may require psychiatric evaluation and treatment. (See also Chapter 10, Trauma and Stressor-Related Disorders, for further discussion of these topics.)

A 75-year-old Catholic female survivor of the Pawiak prison in Warsaw, Poland, and then of a concentration camp after her capture as a member of the underground in World War II stated that she had wanted to become a painter. In camp, she carved the Madonna and Child on her toothbrush and sent it home to her mother. She made other clandestine carvings for several women in her barracks to send home to their families, which pleased everyone. After the war, she became a well-known sculptress with exhibits throughout Europe. Many of her art pieces taught people about suffering and respect for others who are of different religions and cultures.

PHASE OF LIFE PROBLEM

Phase of life problems may occur at any point along the life cycle: the first day of school as a child, the divorce of a parent during adolescence, starting

college as a young adult, marriage, having children, illness, caring for aged parents, and many others. Although, on some level, adults recognize that life events will intrude on expected plans in the course of a lifetime, unexpected, multiple, significant negative occurrences, especially if they are chronic, overwhelm a person's ability to recover and function constructively. The typical phase of life problems include relationship changes, such as a changed significant personal relationship or loss, job crises, and parenthood.

Because of sex-role socialization and consequent cultural expectations, where men appear externally better able to handle these phases of life problems, women, people with lower SES, and minority group members appear more vulnerable to negative experiences, perhaps because they feel less empowered psychologically. Significant life changes precipitate distress in the form of anxiety and depressive symptoms, an inability to express reactive emotions directly, and often difficulties in coping with ongoing or changed life responsibilities.

Individuals with positive attitudes, healthy family and personal relationships, and mature defense mechanisms and coping styles, including essential trust in self and others, good verbal communication skills, a capacity for creative and positive thinking, and the ability to be flexible, reliable, and energetic, appear to be best able to cope with phase of life problems. Furthermore, a capacity for sublimation; adequate financial and work status; solid values; and healthy, feasible goals can enable people to face, accept, and deal realistically with expected and unexpected life problems and changes.

NONCOMPLIANCE WITH TREATMENT

Compliance is the degree to which a patient carries out the recommendations of the treating physician. A positive doctor–patient relationship can help foster compliance, but even in those circumstances, the patient may be reluctant to comply with a physician's advice. In psychiatry, a significant concern is medication noncompliance, which may result from discomforting side effects, expense, personal value judgments, and denial of illness, among many others. We should only use this category when the problem is sufficiently severe to warrant independent clinical attention.

RELATIONAL PROBLEMS

An adult's psychological health and sense of well-being depend, to a significant degree, on the quality of his or her critical relationships—that is, on patterns of interaction with a partner and children, parents and siblings, and friends and colleagues. Problems in the interaction between any of these significant others can lead to clinical symptoms and impaired functioning among one or more members of the relational unit. Relational problems may be a focus of clinical attention (1) when a relational unit is distressed and dysfunctional or threatened with dissolution and (2) when the relational problems precede, accompany, or follow other psychiatric or medical disorders. Indeed, the relational context of the patient influences other medical or psychiatric symptoms. Conversely, the functioning of a relational unit is affected by a member's general and other medical or psychiatric illness. Relational disorders require a different clinical approach than other disorders. Instead of focusing primarily on the link between symptoms, signs, and the workings of the individual mind, the clinician must also focus on interactions between the individuals involved. Also, the clinician should consider how these interactions are related to the general and other medical or psychiatric symptoms in a meaningful way.

Definition

Relational problems are patterns of interaction between members of a relational unit that are associated with significantly impaired functioning in one or more individual members. Thus one may have parent–child problems, sibling-related problems, or other dyad or triad impairments. At times the entire unit, such as the family itself, may be dysfunctional.

Epidemiology

No reliable figures are available on the prevalence of relational problems. They can be assumed to be ubiquitous; however, most relational problems resolve without professional intervention. We should consider the nature, frequency, and effects of the problem on those involved before using this diagnosis. For example, divorce, which occurs in just under 50 percent of marriages, is a problem that partners resolve through the remedy of divorce.

We do not need to use this diagnosis for most divorces. If the persons cannot resolve their disputation and continue to live together in a sadomasochistic or pathologically depressed relationship with unhappiness and abuse, then they should be so labeled. Relationship problems between involved persons that cannot be resolved by friends, family, or clergy require professional intervention by psychiatrists, clinical psychologists, social workers, and other mental health professionals.

Relational Problem Related to a Mental Disorder or General Medical Condition

When a family member is ill either from a psychiatric or medical illness, there are reverberations throughout the family unit. Studies indicate that whereas satisfying relationships may have a health-protective influence, relationship distress tends to be associated with an increased incidence of illness. Psychophysiologic mechanisms help to explain how relational systems affect physical or mental health—for example, the intense emotions generated in human attachment systems can affect vascular reactivity and immune processes. Thus, stress-related psychological or physical symptoms can be an expression of family dysfunction.

Adults must often assume responsibility for caring for aging parents while they are still caring for their children, and this dual obligation can create stress. When adults take care of their parents, both parties must adapt to a reversal of their former roles, and the caretakers not only face the potential loss of their parents but also must cope with evidence of their mortality.

Some caretakers abuse their aging parents, a problem that is now receiving attention. Abuse is most likely to occur when the caretaking offspring have substance abuse problems, are under economic stress, and have no relief from their caretaking duties or when the parent is bedridden or has a chronic illness requiring constant nursing attention. Women suffer abuse more often than men, and most abuse occurs in persons older than age 75 years.

The development of chronic illness in a family member stresses the family system and requires adaptation by both the sick person and the other family members. The person who has become sick must frequently face a loss of autonomy, an increased sense of vulnerability, and sometimes a taxing medical regimen. The other family members must experience the loss of the

person as he or she was before the illness, and they usually have substantial caretaking responsibility—for example, in debilitating neurologic diseases, including dementia of the Alzheimer's type, and diseases such as AIDS and cancer. In these cases, the whole family must deal with the stress of prospective death as well as the current illness. Some families use the anger engendered by such situations to create support organizations, increase public awareness of the disease, and rally around the sick member. However, chronic illness frequently produces depression in family members and can cause them to withdraw from or attack one another. The burden of caring for ill family members falls disproportionately on the women in a family—mothers, daughters, and daughters-in-law.

Chronic emotional illness also requires major adaptations by families. For instance, family members may react with chaos or fear of the psychotic productions of a family member with schizophrenia. The regression, exaggerated emotions, frequent hospitalizations, and economic and social dependence of a person with schizophrenia can stress the family system. Family members may react with hostile feelings (referred to as expressed emotion) that are associated with a poor prognosis for the person who is sick. Similarly, a family member with bipolar I disorder can disrupt a family, particularly during manic episodes.

Family devastation can occur when illness (1) suddenly strikes a previously healthy person, (2) occurs earlier than expected in the life cycle (some impairment of physical capacities is expected in old age, although many older persons are healthy), (3) affects the economic stability of the family, and (4) when there are few options for improving the condition of the sick family member.

Parent–Child Relational Problem

Parents differ widely in sensing the needs of their infants. Some quickly note their child's moods and needs; others are slow to respond. Parental responsiveness interacts with the children's temperament to affect the quality of the attachment between child and parent. The diagnosis of the parent–child relational problem applies when the focus of clinical attention is a pattern of interaction between parent and child that is associated with clinically significant impairment in individual or family functioning or with clinically

significant symptoms. Examples include impaired communication, overprotection, and inadequate discipline.

Research on parenting skills has isolated two primary dimensions: (1) a permissive–restrictive dimension and (2) a warm and accepting versus a cold and hostile dimension. A typology that separates parents on these dimensions distinguishes among *authoritarian* (restrictive and cold), *permissive* (minimally restrictive and accepting), and *authoritative* (restrictive as needed but also warm and accepting) parenting styles. Children of authoritarian parents tend to be withdrawn or conflicted; those of permissive parents are likely to be more aggressive, impulsive, and low achievers; and children of authoritative parents seem to function at the highest level, socially and cognitively. However, switching from an authoritarian to a permissive mode may create a negative reinforcement pattern.

Difficulties in many situations stress the usual parent–child interaction. Substantial evidence indicates that marital discord leads to problems in children, from depression and withdrawal to conduct disorder and poor performance at school. Parents may resort to *triangulation*, where they recruit a child as an ally in the struggle with the partner. Divorces and remarriages stress the parent–child relationship and may create painful loyalty conflicts. Stepparents often find it challenging to assume a parental role and may resent the special relationship that exists between their new marital partner and the children from that partner's previous marriages. The resentment of a stepparent by a stepchild and the favoring of a natural child are usual reactions in a new family's initial phases of adjustment. When a second child is born, both familial stress and happiness may result, although happiness is the dominant emotion in most families. The birth of a child can also be troublesome when parents had adopted a child in the belief that they were infertile. Single-parent families usually consist of a mother and children, and their relationship is often affected by financial and emotional problems.

Other situations that can produce a parent–child problem are the development of fatal, disabling, or chronic illness, such as leukemia, epilepsy, sickle-cell anemia, or spinal cord injury, in either the parent or child. The birth of a child with congenital disabilities, such as cerebral palsy, blindness, or deafness, may also produce parent–child problems. These situations, which are not rare, challenge the emotional resources of those involved. Parents and the child must face present and potential loss and must

adjust their day-to-day lives physically, economically, and emotionally. These situations can strain the healthiest families and produce parent–child problems not only with the sick person but also with the unaffected family members. In a family with a severely sick child, parents may resent, prefer, or neglect the other children because the ill child requires much time and attention.

Parents with children who have emotional disorders face particular problems, depending on the child's illness. In families with a child with schizophrenia, family treatment is beneficial and improves the social adjustment of the patient. Similarly, family therapy is useful when a child has a mood disorder. In families with a substance-abusing child or adolescent, family involvement is crucial to help control the drug-seeking behavior and to allow family members to verbalize the feelings of frustration and anger that are invariably present.

Normal developmental crises can also be related to parent–child problems. For instance, adolescence is a time of frequent conflict as the adolescent resists rules and demands, increasing autonomy and, at the same time, elicits protective control by displaying immature and dangerous behavior.

The parents of sons ages 18, 15, and 11 years presented with distress about the behavior of their middle child. The family had been cohesive with satisfactory relationships among all members until 6 months before this consultation. At that time, the 15-year-old son began seeing a girl from a comparatively unsupervised household. Frequent arguments had developed between parents and son regarding going out on school nights, curfews, and neglect of schoolwork. The son's combativeness and lowered academic achievement upset his parents to a great deal. They had not experienced similar conflicts with their oldest child. The adolescent, however, maintained a good relationship with his siblings and friends, did not have behavior problems at school, continued to participate in the school basketball team, and was not a substance user.

Daycare Centers. Quality of care during the first 3 years of life is crucial to neuropsychologic development. The National Institute of Child Health and Human Development does not consider daycare harmful to children,

especially when the caregivers and daycare teachers provide consistent, empathetic, nurturing care. Not all daycare centers can meet that level of care, however, especially those located in impoverished urban areas. Children receiving less than optimal caring exhibit decreased intellectual and verbal skills that indicate delayed neurocognitive development. They may also become irritable, anxious, or depressed, which interferes with the parent–child bonding experience, and they are less assertive and less effectively toilet trained by the age of 5 years.

Currently, more than 55 percent of women are in the workforce, many of whom have no choice but to place their children in daycare centers. Close to 50 percent of entering medical students are women; few medical centers, however, make adequate provisions for on-site daycare centers for their students or staff. Similarly, corporations need to provide on-site, high-quality care for the children of their employees. Not only will that approach benefit the children, but also corporate economic benefits will accrue as a result of reduced absenteeism, increased productivity, and happier working mothers. Such programs have the added benefit of decreasing stresses on marriages.

Partner Relational Problem

Partner relational problems may include negative communication (e.g., criticisms), distorted communication (e.g., unrealistic expectations), or noncommunication (e.g., withdrawal) associated with clinically significant impairment in individual or family functioning or symptoms in one or both partners.

When persons have partner relational problems, psychiatrists must assess whether a patient's distress arises from the relationship or a mental disorder. Mental disorders are more common in single persons—those who never married or who are widowed, separated, or divorced—than among married persons. Clinicians should evaluate developmental, sexual, and occupational and relationship histories, for purposes of diagnosis.

Marriage demands a sustained level of adaptation from both partners. In a troubled marriage, a therapist can encourage the partners to explore areas such as the extent of communication between the partners, their ways of solving disputes, their attitudes toward childbearing and child-rearing, their relationships with their in-laws, their attitudes toward social life, their

handling of finances, and their sexual interaction. The birth of a child, abortion or miscarriage, economic stresses, moves to new areas, episodes of illness, significant career changes, and any situations that involve a significant change in marital roles can precipitate stressful periods in a relationship. Illness in a child exerts the most significant strain on a marriage, and marriages in which a child has died through illness or accident more often than not end in divorce. Complaints of lifelong anorgasmia or impotence by marital partners usually indicate intrapsychic problems, although sexual dissatisfaction is involved in many cases of marital maladjustment.

Adjustment to marital roles can be a problem when partners are from different backgrounds and have grown up with different value systems. For example, members of low SES groups perceive a wife as making most of the decisions in the family, and they accept physical punishment as a way to discipline children. Middle-class persons perceive family decision-making processes as shared, with the husband often being the final arbiter, and they prefer to discipline children verbally. Therapists and partners can handle the problems involving conflicts in values, adjustment to new roles, and poor communication by examining the couple's relationship, as in marital therapy.

Epidemiologic surveys show that unhappy marriages are a risk factor for major depressive disorders. Marital discord also affects physical health. For example, in a study of women age 30 to 65 years with coronary artery disease, marital stress worsened the prognosis 2.9 times for recurrent coronary events. Marital conflict was also associated with a 46 percent higher relative death risk among female patients having hemodialysis and with elevations in serum epinephrine, norepinephrine, and corticotrophin levels in both men and women. In one study, patients with high levels of hostile marital behavior had slower healing wounds, lower production of proinflammatory cytokines, and higher cytokine production in peripheral blood. Overall, women show better psychological and physiologic responsiveness to conflict than men.

Physician Marriages. Physicians have a higher risk of divorce than other occupational groups. The incidence of divorce among physicians is about 25 to 30 percent. Specialty choice influenced divorce. The highest rate of divorce occurred in psychiatrists (50 percent) followed by surgeons (33

percent) and internists, pediatricians, and pathologists (31 percent). The average age at first marriage was 26 years among all groups.

It is not clear why physicians are at high risk for divorce. Factors implicated include the stresses of dealing with dying patients, making life-and-death decisions, working long hours, and the constant risk of malpractice litigation. Such stressors may predispose physicians to a variety of emotional ills, with the most common being depression and substance abuse, including alcoholism. Such persons generally cannot deal with the complex interactions required to maintain successful long-term relationships of any kind, and marriage requires the most interpersonal skills of all.

Sibling Relational Problem

Sibling relationships tend to be characterized by competition, comparison, and cooperation. Intense sibling rivalry can occur with the birth of a child and can persist as the children grow up, compete for parental approval, and measure their accomplishments against one another. Alliances between siblings are equally common. Siblings may learn to protect one another against parental control or aggression. In households with three children, one pair tends to become tightly involved with one another, leaving the extra child in the position of an outsider.

Relational problems can arise when a family treats siblings unequally; for instance, idealizing one child while casting another in the role of the family scapegoat. Differences in gender roles and expectations expressed by the parents can underlie sibling rivalry. Parent–child relationships also are dependent on personality interactions. A child's resentment directed at a parental figure or a child's own disavowed dark emotions can be projected onto a sibling and can fuel an intense hate relationship.

An ill child creates stress for the child's siblings. Parental concern and attention to the sick child can elicit envy in the siblings. Also, chronic disability can leave the sick child feeling devalued and rejected by siblings, and the latter may develop a sense of superiority and may feel embarrassed about having a disabled sister or brother. Twin relationships have become an area of increasing study. Preliminary data show that twins are more likely to be cooperative than competitive. Whether or not identical twins should be dressed differently during their toddler years to ensure a separate identity is

open to question as is the issue of whether or not they should be in separate classrooms when they begin school.

Other Relational Problems

People, across the life cycle, may become involved in relational problems with leaders and others in their communities at large. In such relationships, conflicts are frequent and can bring about stress-related symptoms. Many relational problems of children occur in the school setting and involve peers. Impaired peer relationships can be the chief complaint in attention-deficit or conduct disorders, as well as in depressive and other psychiatric disorders of childhood, adolescence, and adulthood.

Racial, ethnic, and religious prejudices and ignorance cause problems in interpersonal relationships. In the workplace and communities at large, sexual harassment is often a combination of inappropriate sexual interactions, inappropriate displays of abuse of power and dominance, and expressions of negative gender stereotypes. This harassment most often victimizes women and gay men. However, it can also affect children and adolescents of both sexes.

B Treatment Across the Lifespan

Psychopharmacology

Psychopharmacologic advances continue to expand the parameters of psychiatric treatments dramatically. Our increasing understanding of the brain has led to more effective, less toxic, better-tolerated, and more specific therapeutic agents. With the ever-increasing sophistication and array of treatment options, clinicians, however, must remain aware of potential adverse effects, drug–drug (and drug–food or drug–supplement) interactions, and how to manage the emergence of unwanted or unintended consequences. Newer drugs often cause side effects that are not recognized initially. Keeping up with the latest research findings is important as these findings proliferate. A thorough understanding of the management of medication-induced side effects (either through treating the effect with another agent or substituting another primary agent) is necessary.

Medications used to treat psychiatric disorders are sometimes referred to as *psychotropic drugs*. These drugs are commonly described by their primary clinical application, for example, *antidepressants, antipsychotics, mood stabilizers, anxiolytics, hypnotics, cognitive enhancers,* and *stimulants*. A problem with this approach is that, in many instances, drugs have multiple indications. For example, drugs such as the selective serotonin reuptake inhibitors (SSRIs) are both antidepressants and anxiolytics, and the serotonin-dopamine antagonists (SDAs) are both antipsychotics and mood stabilizers. The term is largely synonymous with simply "psychiatric drugs" and we use both terms synonymously in this book.

Psychotropic drugs have also been organized according to structure (e.g., tricyclic), mechanism (e.g., monoamine oxidase inhibitor [MAOI]), history (e.g., first-generation, traditional), uniqueness (e.g., atypical), or indication (e.g., antidepressant). A further source of confusion is that many drugs used

to treat medical and neurologic conditions are routinely used to treat psychiatric disorders.

Also, psychotropic drug terminology can be confusing. The first pharmaceutical agents used to treat schizophrenia were termed *tranquilizers*. When newer drugs emerged as therapies for anxiety, a distinction was drawn between *major* and *minor tranquilizers*. At first, antidepressants were tricyclic antidepressants (TCAs) or MAOIs. In the 1970s and 1980s, as newer antidepressant drugs emerged, they were labeled as *second-* or *third-generation antidepressants*. More recently, older agents used as treatments for psychosis became known as *typical, conventional,* or first-generation *traditional* neuroleptics. Newer ones became *atypical neuroleptics* or second-generation antipsychotics.

In this chapter, we still start with a general review of psychopharmacology, as it applies to psychotropic medications. We will then review the major classes of drugs. For the purposes here, we will use the first system of organization described above; that is, we will classify them by their primary application. Also, we will divert from our usual practice of mainly using generic names of the drugs to, in many cases, include brand names as well. However, in practice, most psychotropic medications are now available through generic preparations, and few patients receive the brand version of a medication. Also, the brand names here reflect US brands. Drug companies in other countries may produce medications under a different brand name.

DRUG SELECTION

Although all U.S. Food and Drug Administration (FDA)-approved psychotropics are similar in overall effectiveness for their indicated disorder, they differ considerably in their pharmacology and their efficacy and adverse effects on individual patients. The ability of a drug to prove effective, thus, is only partially predictable and is dependent on poorly understood patient variables. Nevertheless, some drugs may have a niche in which they can be uniquely helpful for a subgroup of patients, without demonstrating any overall superiority in efficacy. No drug is universally effective, and no evidence indicates the unambiguous superiority of any single agent as a treatment for any major psychiatric disorders. The only exception, clozapine (Clozaril), has been approved by the FDA as a treatment for cases of

treatment-refractory schizophrenia.

Decisions about drug selection and use are made on a case-by-case basis, relying on individual judgment by the physician. Other factors in drug selection are the characteristics of the drug and the nature of the patient's illness. Each of these components affects the probability of a successful outcome.

DRUG FACTORS

Pharmacodynamics

Both genetic and environmental factors influence individual response to and tolerability of psychotropic agents. Thus, a drug that may not prove effective in many patients with a disorder can dramatically improve symptoms in others. In these cases, identification of characteristics that might predict potential candidates for that drug becomes important but often remains elusive.

Drugs, even within the same class, are distinguished from one another by often subtle differences in molecular structure, types of interactions with neurotransmitter systems, differences in pharmacokinetics, the presence or absence of active metabolites, and protein binding. These differences, along with patient biochemical variations, account for the profile of efficacy, tolerability, and safety and the risk-to-benefit ratio for the individual. These multiple variables, some poorly understood, make it difficult to predict a drug's effect with certainty. Nevertheless, knowledge of the nature of each property increases the likelihood of successful treatment. The clinical effects of drugs are best understood in terms of *pharmacokinetics* and *pharmacodynamics*. Pharmacokinetics describes *what the body does to a drug,* whereas pharmacodynamic*s is *what the drug does to the body*.

Pharmacokinetics and pharmacodynamics need to be seen in the context of the underlying variability among patients for how drug effects are expressed clinically. Patients differ in their therapeutic response to a drug, and the experience of side effects. It is increasingly clear that these differences have a strong genetic basis. Pharmacogenetics research is attempting to identify the role of genetics in drug response.

Primary pharmacodynamic considerations include receptor mechanisms,

the dose–response curve, the therapeutic index, and the development of tolerance, dependence, and withdrawal phenomena. The drug's mechanism of action is subsumed under pharmacodynamics. The clinical response to a drug, including adverse reactions, results from an interaction between that drug and a patient's susceptibility to those actions. Pharmacogenetic studies are beginning to identify genetic polymorphisms linked to individual differences in treatment response and sensitivity to side effects.

Mechanisms

The mechanisms through which most psychotropic drugs produce their therapeutic effects remain poorly understood. Standard explanations focus on ways that drugs alter synaptic concentrations of dopamine, serotonin, norepinephrine, histamine, γ-aminobutyric acid (GABA), or acetylcholine. These changes are said to result from receptor antagonists or agonists, interference with neurotransmitter reuptake, enhancement of neurotransmitter release, or inhibition of enzymes. Specific drugs are associated with permutations or combinations of these actions. For example, a drug can be an agonist for a receptor, thus stimulating the specific biologic activity of the receptor, or an antagonist, thus inhibiting the biologic activity. Some drugs are partial agonists because they are not capable of fully activating a specific receptor. Some psychotropic drugs also produce clinical effects through mechanisms other than receptor interactions. For example, lithium (Eskalith) can act by directly inhibiting the enzyme inositol-1-phosphatase. Some effects are closely linked to a specific synaptic effect. For example, most medications that treat psychosis share the ability to block the dopamine type 2 (D_2) receptor. Similarly, benzodiazepine agonists bind a receptor complex that contains benzodiazepine and GABA receptors.

Additionally, illustrating the fact that the mechanisms of action of psychotropic drugs remain only partially understood are observations that medications that do not directly target monoamine neurotransmitters can be remarkably effective in treating some psychiatric disorders. For example, ketamine (Ketalar), an anesthetic agent that targets glutamate, can rapidly and dramatically alleviate symptoms of depression when given as a slow infusion. Another example involves the antibiotic minocycline (Solodyn), which has been shown to have antidepressant effects. Along with other findings, this

suggests that the immune system and inflammatory responses may underlie some mood disorders.

Accounts of the so-called mechanisms of action should nevertheless be kept in perspective. Explanations of how psychotropic drugs work that focus on synaptic elements represent an oversimplification of a complex series of events. If merely raising or lowering levels of neurotransmitter activity is associated with the clinical effects of a drug, then all drugs that cause these changes should produce equivalent benefits. This predictability is not the case. Multiple obscure actions, several steps removed from events at neuronal receptor sites, are probably responsible for the therapeutic effects of psychotropic drugs. These *downstream* elements are postulated to represent the actual reasons that these drugs produce clinical improvement. A glossary of terms related to receptor drug interactions is given in Table 21-1.

SIDE EFFECTS

Side effects are an unavoidable risk of medication treatment. Although it is impossible to have an encyclopedic knowledge of all possible adverse drug effects, prescribing clinicians should be familiar with the more common adverse effects, as well as those with serious medical consequences. No single text or document, including the product information, contains a complete list of possible treatment-emergent events.

Side effect considerations include the probability of its occurrence, its impact on a patient's quality of life, its time course, and its cause. Just as no one drug is sure to produce clinical improvement in all patients, no side effect, no matter how common, occurs in every patient. When concurrent medical disorders or a history of a similar adverse reaction puts a patient at increased risk for a side effect, it is logical to consider prescribing a compound not typically associated with that adverse reaction.

Side effects can result from the same pharmacologic action that is responsible for a drug's therapeutic activity or from an unrelated property. In examples of the latter, some of the most common adverse effects of the TCAs are caused by blockade of muscarinic acetylcholine receptors or histamine receptors. If a patient is sensitive to these effects, alternative agents without these properties should be prescribed. When side effects are manifestations of the drug's presumed mechanism of action, side effects may be unavoidable.

Thus, blockade of serotonin reuptake by SSRIs can cause nausea and sexual dysfunction. The D_2 blockade of drugs used to treat psychosis can cause extrapyramidal side effects. Agonist action of benzodiazepine receptors can cause ataxia and daytime sleepiness. In these cases, additional medications are frequently used to make the primary agent better tolerated.

Time Course

Adverse effects differ in terms of their onset and duration. Some side effects appear at the outset of treatment and then rapidly diminish. Nausea occurring with SSRIs or venlafaxine (Effexor) and sedation occurring with mirtazapine (Remeron) are good examples of early, time-limited side effects. Early-onset, but persistent, side effects include a dry mouth that is associated with noradrenergic reuptake inhibition or antimuscarinic activity. Some side effects appear later in treatment (*late-appearing side effects*) and, sometimes may be just the opposite of adverse events early in treatment. For example, patients may typically lose weight during early treatment with SSRIs, only to find, over time, a reversal occurs, so that they gain weight.

Similarly, early activation or agitation may be followed by constant fatigue or apathy. Because most data about new drugs come from short-term studies, generally 8 weeks in duration, early-onset side effects are overrepresented in product information and descriptions of newly marketed information. Clinicians must follow the letters to the editor sections of journals and other sources of information to update their understanding of the real side effect profile of a drug.

Adverse effects differ in their impact on compliance and the potential to cause harm. Depending on a patient's threshold of tolerance for a side effect and the impact on the quality of life, side effects can lead to drug discontinuation. Examples of serious side effects include agranulocytosis (clozapine), Stevens–Johnson syndrome (lamotrigine [Lamictal]), hepatic failure (nefazodone [Serzone]), stroke (phenelzine [Nardil]), and heart block (thioridazine [Mellaril]). Overall, the risk of life-threatening side effects with psychotropics is low. Drugs that carry such a risk should be monitored more closely, and the prescribing physician should take into account whether the potential clinical benefits justify the additional risk. Any drug with a serious risk, as reflected in a black box warning, is generally used less extensively

than would otherwise be the case.

Table 21-1
Glossary of Receptor Drug Interactions

Receptor Interaction	Definition	Examples and Comments
Agonist (full agonist)	A drug or medication that binds to a specific receptor producing an effect identical to that usually produced by the neurotransmitter affecting that receptor. Drugs are often designed as receptor agonists to treat a variety of diseases and disorders in which the original neurotransmitter is missing or diminished.	Full agonists include opioids such as morphine, methadone, oxycodone, hydrocodone, heroin, codeine, meperidine, propoxyphene, and fentanyl. Benzodiazepines act as agonists at the GABA receptor complex.
Antagonist	A compound that binds to a receptor that blocks or reduces the action of another substance (agonist) at the receptor site involved. Antagonists that compete with an agonist for a receptor are *competitive antagonists* Those that antagonize by other means are *noncompetitive antagonists*	Flumazenil is a competitive benzodiazepine receptor antagonist. It competitively inhibits the activity at the benzodiazepine recognition site on the GABA/benzodiazepine receptor complex. It is the purest antagonist synthesized. Drugs used in the treatment of schizophrenia block dopamine 2 receptors. Examples of opioid

		antagonists include naltrexone and naloxone.
Partial agonist (mixed agonist)	A compound that (even when fully occupying a receptor) possesses affinity for a receptor, but elicits a partial pharmacologic response at the receptor involved. Partial agonists are often structural analogs of agonist molecules. If neurotransmitter concentrations are low, partial agonists may behave as an agonist. This is why these medications are sometimes called mixed agonists.	Buprenorphine is a partial agonist that produces typical opioid agonist effects and side effects, such as euphoria and respiratory depression, but its maximal effects are less than those of full agonists like heroin and methadone. When used at low doses buprenorphine produces sufficient agonist effect to enable opioid-addicted individuals to discontinue the drugs with fewer withdrawal symptoms.
Inverse agonist	An inverse agonist is an agent that binds to the same receptor as an agonist for that receptor but produces the opposite pharmacologic effect.	Several inverse agonists are currently in clinical development. One particular example is R015-4513, which is the inverse agonist of the benzodiazepine class of drugs. R015-4513 and the benzodiazepines both utilize the same GABA binding site on neurons, yet R015-4513 has the opposite effect, producing severe anxiety rather than the sedative and anxiolytic

effects associated with benzodiazepines. Cannabinoid inverse agonists have been found to reduce appetite, the opposite of the craving effect associated with cannabis.

GABA, γ-aminobutyric acid.
Table by Norman Sussman, M.D.

In the case of haloperidol (Haldol) and other dopamine receptor antagonists (DRAs), long-term complications, such as tardive dyskinesia, have been well documented. Emerging evidence also suggests that the use of dopamine antagonists is associated with a small increase in the risk of breast cancer and that this is related to larger cumulative doses. In cases in which serious risk is associated with a drug, closer medical monitoring of medication treatment is warranted. Because the most widely used psychotropics, such as the SSRIs and SDAs, have only been in use since the 1980s or 1990s, there is less certainty about long-term effects, but no evidence indicates that side effects are not merely extensions of those already evident during initial therapy. It should also be kept in mind that most drugs used in the treatment of chronic medical disorders have not been in use sufficiently long to provide assurances about unintended long-term adverse effects.

Suicidal Ideation and Antidepressant Treatment

The issue of antidepressant-associated suicide has become front-page news, the result of an analysis suggesting a link between medication use and suicidal ideation among children, adolescents, and adults up to age 24 in short-term (4 to 16 weeks), placebo-controlled trials of nine newer antidepressant drugs. The data from trials involving more than 4,400 patients suggested that the average risk of suicidal thinking or behavior (suicidality) during the first few months of treatment in those receiving antidepressants was 4 percent, twice the placebo risk of 2 percent. No suicides occurred in

these trials. The analysis also showed no increase in suicide risk among the 25- to 65-age group. Antidepressants reduced suicidality among those over age 65.

Following public hearings on the subject, in October 2004, the FDA requested the addition of black box warnings—the most severe warning placed on the labeling of prescription medication—to all antidepressant drugs, old and new. This action raised the alarm among parents and physicians and prompted an explosion of advertisements by malpractice attorneys. Most important, antidepressant prescriptions written for adolescents declined, whereas those for adults flattened, after years of growth.

A large study of real-world patients published in the January 2006 issue of the *American Journal of Psychiatry* raised severe doubt about antidepressants and actual suicidality and about the wisdom of the FDA's decision to change the labeling. The study examined suicides and hospitalizations for suicide attempts in the medical records of 65,103 members of a nonprofit insurer in the Pacific Northwest that covers about 500,000 people who received antidepressants from 1992 to 2003. It found that (1) newer antidepressants were associated with a more rapid and more significant reduction in risk than older types of antidepressants, and (2) patients were significantly more likely to attempt or commit suicide in the month before they began drug therapy than in the 6 months after starting it.

This controversy is not the first time credible evidence has contradicted a significant link between antidepressant use and increased risk of suicide. At the hearings that led to the black box warning, John Mann of Columbia University presented population data showing that since 1987, the year before fluoxetine (Prozac) became the first marketed SSRI, suicide rates in the United States began dropping and that areas in the United States with the highest SSRI prescription rates had the most significant decline in suicides. For every 10 percent increase in prescription rates, the US suicide rate declined 3 percent.

Another study, a review of 588 case files of patients aged 10 to 19, found that a 1 percent increase in antidepressant use was associated with a decrease of 0.23 suicides per 100,000 adolescents per year.

A more critical question, given how slight the risk may be, if indeed it exists, is whether as a result of the FDA's ill-considered actions, some

depressed patients are not getting potentially life-saving treatment. Epidemiologic findings from several countries, including the United States, have shown that decreased prescribing of antidepressants for depressed children and adolescents resulted in an increase in suicide rates in those populations.

Medication-Induced Movement Disorders

Medication-induced movement disorders are commonly associated with the use of psychotropic drugs. Although most frequently associated with drugs that block dopamine type 2 (D_2) receptors, abnormal motor activity may occur with other types of medications as well. Sometimes it can be challenging to determine if abnormal motor movements are an adverse event or a symptom of an underlying disorder. For example, anxiety can resemble akathisia, and alcohol or benzodiazepine withdrawal can cause tremors. The American Psychiatric Association has decided to retain the term *neuroleptic* when discussing side effects associated with drugs used to treat psychosis— the DRAs and second-generation antipsychotics (SGAs). The rationale for continued use of the term is that it was initially used to describe the tendency of these drugs to cause abnormal movements. Note that SGA and SDA are often used interchangeably when referring to the second-generation antipsychotics.

The most common neuroleptic-related movement disorders are parkinsonism, acute dystonia, and acute akathisia. The neuroleptic malignant syndrome is a life-threatening and often misdiagnosed condition. Neuroleptic-induced tardive dyskinesia is a late-appearing adverse effect of neuroleptic drugs and can be irreversible; recent data, however, indicate that the syndrome, although still severe and potentially disabling, is less pernicious than was previously thought in patients taking DRAs. The newer antipsychotics, the SDAs, block binding to dopamine receptors to a much lesser degree and thereby are presumed to be less likely to produce such movement disorders. Nevertheless, this risk remains, and vigilance is still required when these drugs are prescribed.

Table 21-2 lists the selected medications associated with movement disorders and their impact on relevant neuroreceptors.

Neuroleptic-Induced Parkinsonism and Other Medication-Induced Parkinsonism

DIAGNOSIS, SIGNS, AND SYMPTOMS. Symptoms of neuroleptic-induced parkinsonism and other medication-induced parkinsonism include muscle stiffness (lead pipe rigidity), cogwheel rigidity, shuffling gait, stooped posture, and drooling. The pill-
rolling tremor of idiopathic parkinsonism is rare, but a regular, coarse tremor similar to essential tremor may be present. The so-called *rabbit syndrome,* a tremor affecting the lips and perioral muscles, is another parkinsonian effect seen with antipsychotics, although perioral tremor is more likely than other tremors to occur late in the course of treatment.

EPIDEMIOLOGY. Parkinsonian adverse effects typically occur within 5 to 90 days of the initiation of treatment. Patients who are elderly and female are at the highest risk for neuroleptic-induced parkinsonism, although the disorder can occur at all ages.

ETIOLOGY. The blockade of D_2 receptors causes neuroleptic-induced parkinsonism in the caudate at the termination of the nigrostriatal dopamine neurons. All antipsychotics can cause the symptoms, especially high-potency drugs with low levels of anticholinergic activity, most notably haloperidol (Haldol).

DIFFERENTIAL DIAGNOSIS. Included in the differential diagnosis are idiopathic parkinsonism, other organic causes of parkinsonism, and depression, which can also be associated with parkinsonian symptoms. Decreased psychomotor activity and blunted facial expression are symptoms of depression and idiopathic parkinsonism.

TREATMENT. Parkinsonism can be treated with anticholinergic agents, benztropine (Cogentin), amantadine (Symmetrel), or diphenhydramine (Benadryl) (Table 21-3). Anticholinergics should be withdrawn after 4 to 6 weeks to assess whether tolerance to the parkinsonian effects has developed; about half of patients with neuroleptic-induced parkinsonism require continued treatment. Even after the antipsychotics are withdrawn, parkinsonian symptoms can last up to 2 weeks. In elderly patients, this may

last as long as 3 months. With such patients, the clinician may continue the anticholinergic drug after the antipsychotic has been stopped until the parkinsonian symptoms resolve completely.

Neuroleptic Malignant Syndrome

DIAGNOSIS, SIGNS, AND SYMPTOMS. *Neuroleptic malignant syndrome* is a life-threatening complication that can occur anytime during antipsychotic treatment. The motor and behavioral symptoms include muscular rigidity and dystonia, akinesia, mutism, obtundation, and agitation. The autonomic symptoms include hyperthermia, diaphoresis, and increased pulse and blood pressure (BP). Laboratory findings include an increased white blood cell (WBC) count and increased levels of creatinine phosphokinase, liver enzymes, plasma myoglobin, and myoglobinuria, occasionally associated with renal failure.

Table 21-2
Selected Medications Associated with Movement Disorders: Impact on Relevant Neuroreceptors

Type (Subtype)	Name (Brand)	D₂ Blockade	5-HT₂ Blockade	mACh Blockade
Antipsychotics				
Phenothiazine (Aliphatic)	Chlorpromazine (Thorazine)	Low	High	High
Phenothiazine (Piperidines)	Thioridazine (Mellaril)	Low	Med	High
	Mesoridazine (Serentil)	Low	Med	High
Phenothiazine (Piperazines)	Trifluoperazine (Stelazine)	Med	Med	Med
	Fluphenazine (Prolixin)	High	Low	Low
	Perphenazine (Trilafon)	High	Med	Low
Thioxanthenes	Thiothixene (Navane)	High	Med	Low
	Chlorprothivene (Taractan)	Med	High	Med
Dibenzoxazepines	Loxapine (Loxitane)	Med	High	Low
Butyrophenones	Haloperidol (Haldol)	High	Low	Low
	Droperidol (Inapsine)	High	Med	—
Diphenyl-butylpiperidines	Pimozide (Orap)	High	Med	Low
Dihydroindolones	Molindone (Moban)	Med	Low	Low
Dibenzodiazepines	Clozapine (Clozaril)	Low	High	High
Benzisoxazole	Risperidone (Risperdal)	High	High	Low
Thienobenzodiazepines	Olanzapine (Zyprexa)	Low	High	High
Dibenzothiazepines	Quetiapine (Seroquel)	Low/med	Low/med	Low
Benzisothiazolvils	Ziprasidone (Geodon)	Med	High	Low
Quinolones	Aripiprazole (Abilify)	High (as partial agonist)	High	Low
Nonantipsychotic psychotropics	Lithium (Eskalith)	N/A	N/A	N/A
Anticonvulsants		Low	Low	Low
Antidepressants		Low (except amoxapine)	(Varies)	(Varies)
Nonpsychotropics	Prochlorperazine (Compazine)	High	Med	Low
	Metoclopramide (Reglan)	High	High	—

D₂, dopamine type 2; 5-HT₂, 5-hydroxytryptomine type 2; mACh, muscarinic acetylcholine; N/A, not applicable.
Adapted from Janicak PG, Davis JM, Preskom SH, Ayd Fj Jr. *Principles and Practice of Psychopharmacotherapy*. 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2001, with permission.

EPIDEMIOLOGY. About 0.01 to 0.02 percent of patients treated with antipsychotics develop neuroleptic malignant syndrome. Men are affected more frequently than women, and young patients are affected more commonly than elderly patients. The mortality rate can reach 10 to 20 percent or even higher when depot antipsychotic medications are involved.

COURSE AND PROGNOSIS. The symptoms usually evolve over 24 to 72 hours, and the untreated syndrome lasts 10 to 14 days. The diagnosis is often missed in the early stages, and the withdrawal or agitation may mistakenly be considered to reflect an exacerbation of the psychosis.

TREATMENT. In addition to supportive medical treatment, the most commonly used medications for the condition are dantrolene (Dantrium) and bromocriptine (Parlodel), although amantadine (Symmetrel) is sometimes used (Table 21-4). Bromocriptine and amantadine pose direct DRA effects and may overcome the antipsychotic-induced dopamine receptor blockade.

We should reduce the antipsychotic dose to the lowest effective dose possible. High-potency drugs, such as haloperidol, pose the greatest risk. Antipsychotic drugs with anticholinergic effects seem less likely to cause neuroleptic malignant syndrome. Electroconvulsive therapy (ECT) has been used.

Medication-Induced Acute Dystonia

DIAGNOSIS, SIGNS, AND SYMPTOMS. *Dystonias* are brief or prolonged contractions of muscles that result in obviously abnormal movements or postures, including oculogyric crises, tongue protrusion, trismus, torticollis, laryngeal–pharyngeal dystonias, and dystonic postures of the limbs and trunk. Other dystonias include blepharospasm and glossopharyngeal dystonia; the latter results in dysarthria, dysphagia, and even difficulty in breathing, which can cause cyanosis. Children are particularly likely to evidence opisthotonos, scoliosis, lordosis, and writhing movements. Dystonia can be painful and frightening and often results in noncompliance with future drug treatment regimens.

EPIDEMIOLOGY. Their early-onset characterizes the development of acute dystonic symptoms during treatment with neuroleptics. There is a higher incidence of acute dystonia in men, in patients younger than age 30 years, and patients who were given high dosages of high-potency medications.

ETIOLOGY. Although it is most frequent with intramuscular doses of high-potency antipsychotics, dystonia can occur with any antipsychotic. The mechanism of action is thought to be dopaminergic hyperactivity in the basal ganglia that occurs when the central nervous system (CNS) levels of the antipsychotic drug begin to fall between doses.

**Table 21-3
Drug Treatment of Extrapyramidal Disorders**

Generic Name	Trade Name	Usual Daily Dosage	Indications
Anticholinergics			

Benztropine	Cogentin	PO 0.5–2 mg tid; IM or IV 1–2 mg	Acute dystonia, parkinsonism, akinesia, akathisia
Biperiden	Akineton	PO 2–6 mg tid; IM or IV 2 mg	
Procyclidine	Kemadrin	PO 2.5–5 mg bid-qid	
Trihexyphenidyl	Artane, Tremin	PO 2–5 mg tid	
Orphenadrine	Norflex, Disipal	PO 50–100 mg bid-qid; IV 60 mg	Rabbit syndrome

Antihistamine

Diphenhydramine	Benadryl	PO 25 mg qid; IM or IV 25 mg	Acute dystonia, parkinsonism, akinesia, rabbit syndrome
Amantadine	Symmetrel	PO 100–200 mg bid	Parkinsonism, akinesia, rabbit syndrome

β-Adrenergic Antagonist

Propranolol	Inderal	PO 20–40 mg tid	Akathisia, tremor

α-Adrenergic Antagonist

Clonidine	Catapres	PO 0.1 mg tid	Akathisia

Benzodiazepines			
Clonazepam	Klonopin	PO 1 mg bid	Akathisia, acute dystonia
Lorazepam	Ativan	PO 1 mg tid	
Buspirone	BuSpar	PO 20–40 mg qid	Tardive dyskinesia
Vitamin E	—	PO 1,200–1,600 IU/day	Tardive dyskinesia

PO, orally; IM, intramuscularly; IV, intravenously; bid, twice a day; tid, three times a day; qid; four times a day.

DIFFERENTIAL DIAGNOSIS. The differential diagnosis includes seizures and tardive dyskinesia.

COURSE AND PROGNOSIS. Dystonia can fluctuate spontaneously and respond to reassurance, so the clinician gets the false impression that the movement is hysterical or entirely under conscious control.

**Table 21-4
Treatment of Neuroleptic Malignant Syndrome**

Intervention	Dosing	Effectiveness
Amantadine	200–400 mg PO/day in divided doses	Beneficial as monotherapy or in combination; decrease in death rate
Bromocriptine	2.5 mg PO bid or tid, may increase to a total of 45 mg/day	Mortality reduced as a single or combined agent
Levodopa/carbidopa	Levodopa 50–100 mg/day	Case reports of

	IV as continuous infusion	dramatic improvement
Electroconvulsive therapy	Reports of good outcome with both unilateral and bilateral treatments; response may occur in as few as three treatments	Effective when medications have failed; also may treat underlying psychiatric disorder
Dantrolene	1 mg/kg/day for 8 days, then continue as PO for 7 additional days	Benefits may occur in minutes or hours as a single agent or in combination
Benzodiazepines	1–2 mg IM as test dose; if effective, switch to PO; consider use if underlying disorder has catatonic symptoms	Has been reported effective when other agents have failed
Supportive measures	IV hydration, cooling blankets, ice packs, ice-water enema, oxygenation, antipyretics	Often effective as initial approach early in the episode

PO, orally; bid, twice a day; tid, three times a day; IV, intravenously; IM, intramuscularly.
Adapted from Davis JM, Caroif SN, Mann SC. Treatment of neuroleptic malignant syndrome. *Psychiatr Ann*. 2000;30:325–331, with permission.

TREATMENT. Prophylaxis with anticholinergics or related drugs (outlined in Table 21-3) usually prevents dystonia, although the risks of prophylactic treatment weigh against that benefit. Treatment with intramuscular anticholinergics or intravenous or intramuscular diphenhydramine (Benadryl) (50 mg) almost always relieves the symptoms. Diazepam (Valium) (10 mg intravenously), amobarbital (Amytal), caffeine sodium benzoate, and hypnosis have also been reported to be effective. Although tolerance for the

adverse effects usually develops, it is prudent to change the antipsychotic if the patient is particularly concerned that the reaction may recur.

Medication-Induced Acute Akathisia

DIAGNOSIS, SIGNS, AND SYMPTOMS. *Akathisia* is subjective feelings of restlessness, objective signs of restlessness, or both. Examples include a sense of anxiety, inability to relax, jitteriness, pacing, rocking motions while sitting, and rapid alternation of sitting and standing. Akathisia has been associated with the use of a wide range of psychiatric drugs, including antipsychotics, antidepressants, and sympathomimetics. Once akathisia is recognized and diagnosed, the antipsychotic dose should be reduced to a minimally adequate level. Akathisia may be associated with a poor treatment outcome.

EPIDEMIOLOGY. Middle-aged women are at increased risk of akathisia, and the time course is similar to that for neuroleptic-induced parkinsonism.

TREATMENT. Three necessary steps in the treatment of akathisia are reducing medication dosage, attempting treatment with appropriate drugs, and considering changing the neuroleptic. The most efficacious drugs are β-adrenergic receptor antagonists, although anticholinergic drugs, benzodiazepines, and cyproheptadine (Periactin) may benefit some patients. In some cases of akathisia, no treatment seems to be effective.

Tardive Dyskinesia

DIAGNOSIS, SIGNS, AND SYMPTOMS. *Tardive dyskinesia* is a delayed effect of antipsychotics; it rarely occurs until after 6 months of treatment. The disorder consists of abnormal, involuntary, irregular choreoathetoid movements of the muscles of the head, limbs, and trunk. The severity of the movements ranges from minimal—often missed by patients and their families—to grossly incapacitating. Perioral movements are the most common and include darting, twisting, and protruding movements of the tongue; chewing and lateral jaw movements; lip-puckering; and facial grimacing. Finger movements and hand clenching are also typical. Torticollis, retrocollis, trunk twisting, and pelvic thrusting occur in severe cases. In the most severe cases,

patients may have breathing and swallowing irregularities that result in aerophagia, belching, and grunting. Respiratory dyskinesia has also been reported. Dyskinesia is exacerbated by stress and disappears during sleep.

Table 21-5
Abnormal Involuntary Movement Scale (AIMS) Examination Procedure

Patient Identification	Date

Rated by

Either before or after completing the examination procedure, observe the patient unobtrusively at rest (e.g., in waiting room).

The chair to be used in this examination should be a hard, firm one without arms.

After observing the patient, rate him or her on a scale of 0 (none), 1 (minimal), 2 (mild), 3 (moderate), and 4 (severe), according to the severity of the symptoms.

Ask patient whether there is anything in his or her mouth (e.g., gum, candy) and, if so, to remove it.

Ask patient about the current condition of his or her teeth. Ask patient if he or she wears dentures. Do teeth or dentures bother patient now?

Ask patient whether he or she notices movement in mouth, face, hands, or feet. If yes, ask patient to describe and indicate to what extent movements currently bother patient or interfere with his or her activities.

0 1 2 3 4 Have patient sit in chair with hands on knees, legs slightly apart, and feet flat on floor. (Look at entire body for movement while in this position.)

0 1 2 3 4 Ask patient to sit with hands hanging unsupported—If male, between legs; if female and wearing a dress, hanging over knees. (Observe hands and other body areas.)

0 1 2 3 4 Ask patient to open mouth. (Observe tongue at rest within mouth.) Do this twice.

0 1 2 3 4 Ask patient to protrude tongue. (Observe abnormalities of tongue movement.) Do this twice.

0 1 2 3 4 Ask patient to tap thumb, with each finger, as rapidly as possible for 10–15 seconds; separately with right hand, then with left hand. (Observe facial and leg movements.)

0 1 2 3 4 Flex and extend patient's left and right arms. (One at a time.)

0 1 2 3 4 Ask patient to stand up. (Observe in profile. Observe all body areas again, hips included.)

0 1 2 3 4 [a]Ask patient to extend both arms outstretched in front with palms down. (Observe trunk, legs, and mouth.)

0 1 2 3 4 [a]Have patient walk a few paces, turn, and walk back to chair. (Observe hands and gait.)

Do this twice.

[a]Activated movements.

EPIDEMIOLOGY. Tardive dyskinesia develops in about 10 to 20 percent of patients who are treated for more than a year. About 20 to 40 percent of patients who require long-term hospitalization have tardive dyskinesia. Women are more likely to be affected than men. Children, patients who are more than 50 years of age, and patients with brain damage or mood disorders are also at high risk.

COURSE AND PROGNOSIS. Between 5 and 40 percent of all cases of tardive dyskinesia eventually remit, and between 50 and 90 percent of all mild cases remit. Tardive dyskinesia is less likely to remit in elderly patients than in young patients, however.

TREATMENT. The three basic approaches to tardive dyskinesia are prevention, diagnosis, and management. Prevention is best achieved by using antipsychotic medications only when indicated and in the lowest effective doses. The atypical antipsychotics are associated with less tardive dyskinesia than the older antipsychotics. Clozapine (Clozaril) is the only antipsychotic to have minimal risk of tardive dyskinesia and can even help improve preexisting symptoms of tardive dyskinesia. This quality of the drug may be

due to its low affinity for D_2 receptors and high affinity for 5-hydroxytryptamine (5-HT) receptor antagonism. Patients who are receiving antipsychotics should be examined regularly for the appearance of abnormal movements, preferably with the use of a standardized rating scale (Table 21-5). Patients frequently experience an exacerbation of their symptoms when the DRA is withheld, whereas substitution of an SDA may limit the abnormal movements without worsening the progression of the dyskinesia.

Once tardive dyskinesia is recognized, the clinician should consider reducing the dose of the antipsychotic or even stopping the medication altogether. Alternatively, the clinician may switch the patient to clozapine or one of the new SDAs. In patients who cannot continue taking any antipsychotic medication, lithium (Eskalith), carbamazepine (Tegretol), or benzodiazepines may effectively reduce the symptoms of both the movement disorder and the psychosis. In 2017, the FDA-approved valbenazine (Ingrezza) for the treatment of adults with tardive dyskinesia, making this the first approved medication for tardive dyskinesia.

Tardive Dystonia and Tardive Akathisia. On occasion, dystonia and akathisia emerge late in the course of treatment. These symptoms may persist for months or years despite drug discontinuation or dose reduction.

Medication-Induced Postural Tremor

DIAGNOSIS, SIGNS, AND SYMPTOMS. *Tremor* is a rhythmic alteration in a movement that is usually faster than one beat per second. Fine tremor (8 to 12 Hz) is most common.

EPIDEMIOLOGY. Typically, tremors decrease during periods of relaxation and sleep and increase with stress or anxiety.

ETIOLOGY. Whereas all the above diagnoses specifically include an association with a neuroleptic, a range of psychiatric medications can produce tremors—most notably, lithium, stimulants, antidepressants, caffeine, and valproate (Depakene).

TREATMENT. The treatment involves four principles:

1. The lowest possible dose of the psychiatric drug should be taken.
2. Patients should minimize caffeine consumption.
3. The psychiatric drug should be taken at bedtime to minimize the amount of daytime tremor.
4. β-Adrenergic receptor antagonists (e.g., propranolol [Inderal]) can be given to treat drug-induced tremors.

Other Medication-Induced Movement Disorders

NOCTURNAL MYOCLONUS. *Nocturnal myoclonus* consists of highly stereotyped, abrupt contractions of specific leg muscles during sleep. Patients lack any subjective awareness of the leg jerks. The condition may be present in about 40 percent of persons over 65 years of age. The cause is unknown, but it is a rare side effect of SSRIs.

The repetitive leg movements occur every 20 to 60 seconds, with extensions of the large toe and flexion of the ankle, the knee, and the hips. Frequent awakenings, unrefreshing sleep, and daytime sleepiness are significant symptoms. No treatment for nocturnal myoclonus is universally effective. Benzodiazepines, levodopa (Larodopa), quinine, and, in rare cases, opioids may be useful.

RESTLESS LEG SYNDROME. In *restless leg syndrome,* persons feel deep sensations of creeping inside the calves whenever sitting or lying down. The dysesthesias are rarely painful but are agonizingly relentless and cause an almost irresistible urge to move the legs; thus, this syndrome interferes with sleep and with falling asleep. It peaks in middle age and occurs in 5 percent of the population. The cause is unknown, but it is a rare side effect of SSRIs.

Symptoms are relieved by movement and by leg massage. The dopamine receptor agonists ropinirole (Requip) and pramipexole (Mirapex) are effective in treating this syndrome. Other treatments include the benzodiazepines, levodopa, quinine, opioids, propranolol, valproate, and carbamazepine.

Hyperthermic Syndromes. All the medication-induced movement disorders may be associated with hyperthermia. Table 21-6 lists the various conditions associated with hyperthermia.

Side Effects Associated with Newer Medications

All medications are associated with side effects. The clinician should be aware of these, be able to recognize them, and take appropriate measures to treat them.

Somnolence. Sedation is often an intended effect of many psychotropic drugs, mainly when used to treat insomnia, anxiety, or agitation. Daytime sleepiness, or somnolence, is also an unwanted adverse event, however. It is essential for the clinician to alert patients to the possibility of sedation and to document that the person was advised to exercise caution when operating any type of vehicle or mechanical equipment. Some somnolence results from a carryover of nighttime use of drugs as hypnotics. Even with drugs such as the SSRIs, which are activating for many patients, somnolence can be problematic. In some instances, it results from impairment of sleep quality. Chronic use of SSRIs can cause some patients to experience a subjective sense of fatigue, exhaustion, or yawning, even with adequate amounts of sleep. Management of unwanted somnolence includes adjustment of dose or timing of administration, switching to alternative medications, the addition of small doses of stimulants, or the addition of modafinil (Provigil).

Gastrointestinal Disturbances. The significant gastrointestinal (GI) side effects of the older antidepressant and antipsychotic drugs consisted primarily of constipation and dry mouth, a consequence of their antimuscarinic activity. Most of the newer drugs have little antimuscarinic activity but do have effects on the serotonin system. Most of the body's serotonin is in the GI tract, and serotonergic drugs often cause varying degrees of stomach pain, nausea, flatulence, and diarrhea. In most cases, these side effects are transient, but some persons never accommodate and must switch to another class of drugs. The initial use of lower doses or the use of delayed-release preparations are the most effective strategies for minimizing GI side effects.

Movement Disorders. The introduction of SDAs has dramatically reduced the incidence of medication-induced movement disorders, but varying degrees of dose-related parkinsonism, akathisia, and dystonia still occur. Risperidone (Risperdal) most closely resembles the older agents in terms of these side effects. Olanzapine (Zyprexa) also causes more extrapyramidal

effects than clinical trials suggested. Aripiprazole (Abilify) causes severe akathisia. There have been rare reports of SSRI-induced movement disorders, ranging from akathisia to tardive dyskinesia.

Sexual Dysfunction. The use of psychiatric drugs can be associated with sexual dysfunction—decreased libido, impaired ejaculation and erection, and inhibition of female orgasm. In clinical trials with the SSRIs, the extent of sexual side effects was grossly underestimated because data were based on spontaneous reports by patients. The rate of sexual dysfunction in the original fluoxetine product information, for example, was less than 5 percent. In subsequent studies in which specific questions elicited information about sexual side effects, the rate of SSRI-associated sexual dysfunction was found to be between 35 and 75 percent. In clinical practice, patients are not likely to report sexual dysfunction spontaneously to the physician, so it is essential to ask about this side effect. Also, some sexual dysfunctions may be related to the primary psychiatric disorder.

Table 21-6
Drug-Induced Central Hyperthermic Syndromes[a]

Condition (and Mechanism)	Common Drug Causes	Frequent Symptoms	Possible Treatment[b]	Clinical Course
Hyperthermia (↓ heat dissipation, ↑ heat production)	Atropine, lidocaine, meperidine NSAID toxicity, pheochromocytoma, thyrotoxicosis	Hyperthermia, diaphoresis, malaise	Acetaminophen per rectum (325 mg every 4 hr), diazepam oral or per rectum (5 mg every 8 hr) for febrile seizures	Benign, febrile seizures in children
Malignant hyperthermia (↑ heat production)	NMJ blockers (succinylcholine), halothane	Hyperthermia, muscle rigidity, arrhythmias, ischemia,[c] hypotension, rhabdomyolysis; disseminated intravascular coagulation	Dantrolene sodium (1–2 mg/kg/min IV infusion)[d]	Familial, 10% mortality if untreated
Tricyclic overdose (↑ heat production)	Tricyclic antidepressants, cocaine	Hyperthermia, confusion, visual hallucinations, agitation, hyperreflexia, muscle relaxation, anticholinergic effects (dry skin, pupil dilation), arrhythmias	Sodium bicarbonate (1 mEq/kg IV bolus) if arrhythmia is present, physostigmine (1–3 mg IV) with cardiac monitoring	Fatalities have occurred if untreated
Autonomic hyperreflexia (↑ heat production)	CNS stimulants (amphetamines)	Hyperthermia, excitement, hyperreflexia	Trimethaphan (0.3–7 mg/min IV infusion)	Reversible
Lethal catatonia (↓ heat dissipation)	Lead poisoning	Hyperthermia, intense anxiety, destructive behavior, psychosis	Lorazepam (1–2 mg IV every 4 hr), antipsychotics may be contraindicated	High mortality if untreated
Neuroleptic malignant syndrome (mixed; hypothalamic, ↓ heat dissipation, ↑ heat production)	Antipsychotics (neuroleptics), methyldopa, reserpine	Hyperthermia, muscle rigidity, diaphoresis (60%), leukocytosis, delirium, rhabdomyolysis, elevated CPK, autonomic deregulation, extrapyramidal symptoms	Bromocriptine (2–10 mg every 8 hr orally or nasogastric tube), lysuride (0.02–0.1 mg/hr IV infusion), carbidopa-levodopa (Sinemet) (25/100 PO every 8 hr), dantrolene sodium (0.3–1 mg/kg IV every 6 hr)	Rapid onset, 20% mortality if untreated

NSAID, nonsteroidal anti-inflammatory drug; MAOI, monoamine oxidase inhibitor; NMJ, neuromuscular junction; CNS, central nervous system; CPK, creatine phosphokinase; PO, orally; IV, intravenously.
[a]Boldface indicates features that may be used to distinguish one syndrome from another.
[b]Gastric lavage and supportive measures, including cooling, are required in most cases.
[c]Oxygen consumption increases by 7% for every 1°F increase in body temperature.
[d]Has been associated with idiosyncratic hepatocellular injury, as well as severe hypotension in one case.
From Theoharides TC, Harris RS, Weckstein D. Neuroleptic malignant-like syndrome due to cyclobenzaprine? [letter]. *J Clin Psychopharmacol.* 1995;15:80, with permission.

Nevertheless, if sexual dysfunction emerges after pharmacotherapy has begun and the primary response to treatment has been positive, it may be worthwhile to attempt to treat the symptoms. Long lists of possible antidotes to these side effects have evolved, but few interventions are consistently effective, and few have more than anecdotal evidence to support their use. The clinician and patient should consider the possibility of sexual side effects when selecting a drug and switching treatment to another drug that is less or not at all associated with sexual dysfunction if this adverse effect is not acceptable to the patient.

Weight Gain. Weight gain accompanies the use of many psychotropic drugs as a result of retained fluid, increased caloric intake, decreased exercise, or altered metabolism. Weight gain can also occur as a symptom of a disorder, as in bulimia or atypical depression. In these cases, it may be a sign of

recovery. Treatment-emergent increase in body weight is a common reason for noncompliance with a drug regimen. No specific mechanisms have been identified as causing weight gain, and it appears that the histamine and serotonin systems mediate changes in weight associated with many drugs used to treat depression and psychosis. Metformin (Glucophage) has been reported to facilitate weight loss among patients whose weight gain is attributed to the use of serotonin-dopamine reuptake inhibitors and valproic acid (Depakene). Valproate (Depacon), as well as olanzapine, has been linked to the development of insulin resistance, which could induce appetite increase, with the subsequent weight increase. Weight gain is a noteworthy side effect of clozapine (Clozaril) and olanzapine. Genetic factors that regulate body weight, as well as the related problem of diabetes mellitus, seem to involve the 5-HT$_{2C}$ receptor. There is a genetic polymorphism of the promoter region of this receptor, and patients with a variant allele have less weight gain. Drugs with a strong 5-HT$_{2C}$ affinity would be expected to have a more significant impact on body weight of patients with a polymorphism of the 5-HT$_{2C}$ receptor promoter region.

Weight Loss. Initial weight loss is associated with SSRI treatment but is usually transient, with most weight being regained within the first few months. Bupropion (Wellbutrin) has been shown to cause modest weight loss that is sustained. When combined with diet and lifestyle changes, bupropion can facilitate more significant weight loss. Topiramate (Topamax) and zonisamide (Zonegran), marketed as treatments for epilepsy, sometimes produce substantial, sustained loss of weight.

Glucose Changes. Increased risk of glucose abnormalities, including diabetes mellitus, is associated with weight increase during psychotropic drug therapy. Clozapine and olanzapine are associated with a greater risk than other SDAs of abnormalities in fasting glucose levels, as well as hyperosmolar diabetes and ketoacidosis. This dysregulation of glucose homeostasis appears to be drug-induced and increases glucagon.

Hyponatremia. Hyponatremia is associated with oxcarbazepine (Trileptal) and SSRI treatment, especially in elderly patients. Confusion, agitation, and lethargy are common symptoms.

Cognitive Impairment. Cognitive impairment means a disturbance in the capacity to think. Some agents, such as the benzodiazepine agonists, are recognized as causes of cognitive impairment. Other widely used psychotropics, such as the SSRIs, lamotrigine (Lamictal), topiramate (Topamax), gabapentin (Neurontin), lithium, TCAs, and bupropion, however, are also associated with varying degrees of memory impairment and word-finding difficulties. In contrast to the benzodiazepine-induced anterograde amnesia, these agents cause a more subtle type of absent-mindedness. Drugs with anticholinergic properties are likely to worsen memory performance.

Sweating. Severe perspiration unrelated to ambient temperature is associated with TCAs, SSRIs, and venlafaxine. This side effect is often socially disabling. Attempts can be made to treat this side effect with alpha agents, such as terazosin (Hytrin) and oxybutynin (Ditropan).

Cardiovascular Disturbances. Newer agents are less likely to have direct cardiac effects. Many older agents, such as TCAs and phenothiazines, affected BP and cardiac conduction. Thioridazine (Mellaril), which has been in use for decades, has been shown to prolong the QTc interval in a dose-related manner and may increase the risk of sudden death by delaying ventricular repolarization and causing torsades de pointes. Newer drugs are now routinely scrutinized for evidence of cardiac effects. A promising treatment for psychosis, sertindole (Serlect), was not marketed because the FDA would have required a black box warning. Slight QTc effects noted with ziprasidone (Geodon) delayed the marketing of that drug. Clozapine can cause myocarditis in rare cases.

Rash. Any medication is a potential source of a drug rash. Some psychotropics, such as carbamazepine (Equetro, Tegretol) and lamotrigine, have been linked to an increased risk of severe exfoliative dermatitis. Commonly referred to as Stevens–Johnson syndrome, this condition is a systemic, immune-mediated reaction that can prove fatal or result in permanent scarring or blindness. All patients should be informed about the potential seriousness of widespread lesions that occur above the neck, that involve the mucous membranes, and that may be associated with fever and

lymphadenopathy. If such symptoms manifest, a patient should be instructed at the time that the medication is prescribed to go immediately to an emergency department.

Idiosyncratic and Paradoxical Drug Responses

Idiosyncratic reactions occur in a tiny percentage of patients taking a drug. The reactions are not related to the known pharmacologic properties, and most likely represent a genetically based abnormal sensitivity to a drug. A paradoxical response represents the manifestation of a clinical effect the opposite of what is expected. In March 2007, the FDA reported dissociative-like states associated with certain sedative-hypnotics. These included behaviors such as sleepwalking, binge eating, aggressive outbursts, and night driving, of which the patient was unaware. Table 21-7 lists the drugs required to have warning labels for that effect.

Therapeutic Index

The therapeutic index is a relative measure of the toxicity or safety of a drug and is defined as the ratio of the median toxic dose to the median effective dose. The median toxic dose is the dose at which 50 percent of patients experience a specific toxic effect, and the median effective dose is the dose at which 50 percent of patients have a specified therapeutic effect. When the therapeutic index is high, as it is for haloperidol, it is reflected by the wide range of dosages in which that drug is prescribed. Conversely, the therapeutic index for lithium is relatively low, thus requiring careful monitoring of serum lithium levels in patients for whom the drug is prescribed.

Overdose

Safety in overdose is always a consideration in drug selection. Almost all of the newer agents, however, have a wide margin of safety when taken in overdose. By contrast, a 1-month supply of TCAs could be fatal. The depressed patients they were used to treat are the group most at risk of attempting suicide. Because even the safest drugs can sometimes produce severe medical complications, especially when combined with other agents, clinicians must recognize that the prescribed medication can be used in an attempt to commit suicide. Although it is prudent to write nonrefillable

prescriptions for small quantities, this practice passes along increased copay costs to the patient. Many pharmacy benefit management programs encourage the prescribing of a 3-month supply of medication.

Table 21-7
Sedative-Hypnotics Cited by the U.S. Food and Drug Administration

Drug	Manufacturer
Zolpidem (Ambien/Ambien CR)	Sanofi Aventis
Butabarbital (Butisol Sodium)	MedPointe Pharmaceuticals
Pentobarbital and carbromal (Carbrital)	Parke-Davis
Flurazepam (Dalmane)	Valeant Pharmaceuticals
Quazepam (Doral)	Questcor Pharmaceuticals
Triazolam (Halcion)	Pfizer
Eszopiclone (Lunesta)	Sepracor
Ethchlorvynol (Placidyl)	Abbott
Estazolam (Prosom)	Abbott
Temazepam (Restoril)	Tyco Healthcare
Ramelteon (Rozerem)	Takeda
Secobarbital (Seconal)	Lilly
Zaleplon (Sonata)	King Pharmaceuticals

In cases in which suicide is a significant concern, an attempt should be made to verify that the medication is not being hoarded for a later overdose attempt. Random pill counts or asking a family member to dispense daily doses may be helpful. Some patients attempt suicide just as they are beginning to recover. Large quantities of medications with a low therapeutic index should be prescribed judiciously. Another reason to limit the number of

pills prescribed is the possibility of accidental ingestion of medications by children in the household. Psychotherapeutic medications should be kept in a safe place.

Physicians who work in emergency departments should know which drugs can be hemodialyzed. The issues involved are complex and are not based on any single chemical property of the drug. For example, it is generally presumed that drugs with low protein binding are good candidates for dialysis. Venlafaxine, however, is only 27 percent protein-bound and is too large as a molecule dialyzed. Hemodialysis is useful for treating overdose of lithium and valproic acid.

Pharmacokinetics

Pharmacokinetic drug interactions are the effects of drugs on the plasma concentrations of each other, and *pharmacodynamic drug interactions* are the effects of drugs on the biologic activities of each other. Pharmacokinetic concepts are used to describe and predict the time course of drug concentrations in different parts of the body, such as plasma, adipose tissue, and the CNS. From a clinical perspective, pharmacokinetic methods help explain or predict the onset and duration of drug activity and interactions between drugs that alter their metabolism or excretion.

Pharmacogenetic research focuses on finding variant alleles that alter drug pharmacokinetics and pharmacodynamics. Researchers are attempting to identify genetic differences in how enzymes metabolize psychotropics, as well as CNS proteins directly involved in drug action. Likely, identification of patient genotypes will facilitate the prediction of clinical response to different types of drugs.

Most clinicians need to consult charts or computer programs to determine when potential interactions may occur and, if so, how clinically relevant they may be. Whenever possible, it is preferable to use a medication that produces the minimal risk of drug interactions. Also, it is recommended that prescribers know the interaction profiles of the drugs they most commonly prescribe.

Examples of pharmacokinetic interactions include one drug increasing or decreasing the concentrations of a coadministered compound. These types of interactions can also lead to altered concentrations of metabolites. In some

cases, there may also be interference with the conversion of a drug to its active metabolite. Enormous variability exists among patients concerning pharmacokinetic parameters, such as drug absorption and metabolism. Another type of interaction is represented by interactions involving the kidney. Commonly used medications, such as angiotensin-converting enzyme inhibitors (ACEIs), nonsteroidal anti-inflammatory drugs (NSAIDs), and thiazides, decrease the renal clearance of lithium, increasing the likelihood of severe elevations of lithium. Drug interactions can occur pharmacokinetically or pharmacodynamically.

Pharmacogenetics is being used to study why patients differ in the way they metabolize drugs. In patients who are ultrarapid or extensive metabolizers, the concentrations of a drug may be lower than expected.

PATIENT-RELATED FACTORS

Response to medication and sensitivity to side effects are influenced by factors related to the patient. This response is why there is no one-size-fits-all approach to pharmacologic treatment. Patient-related variables include diagnosis, genetic factors, lifestyle, overall medical status, concurrent disorders, and history of drug response. A patient's attitude toward medication in general, aversion to certain types of side effects, and preference for a specific agent also need to be considered.

Diagnosis

Failure to correctly diagnose a disorder diminishes the likelihood of optimal drug selection. Misdiagnosis not only can result in a missed opportunity, but it also can, at times, produce worsening of symptoms. Inadvertently diagnosing a patient in the depressed phase of bipolar disorder as having unipolar depression can induce mania or rapid cycling. Treatment failure or exacerbation of symptoms should prompt a reassessment of the working diagnosis.

Past Treatment Response

A specific drug should be selected according to the patient's history of drug response (compliance, therapeutic response, adverse effects), the patient's

family history of drug response, the profile of adverse effects for that drug concerning the particular patient, and the prescribing clinician's usual practice. If a drug has previously been effective in treating a patient or a family member, the same drug should be used again. For reasons that are not understood, however, some patients fail to respond to a previously effective agent when it is resumed. A history of severe adverse effects from a specific drug is a strong indicator that the patient would not be compliant with that particular drug.

It is helpful if patients can recall the details of past psychotropic drug treatment: the drugs prescribed, in what dosages, for how long, and in what combinations. Because of their psychiatric disorders, many patients, however, are poor historians. If possible, patients' medical records should be obtained to confirm their reports. Family members are a good source of collateral information.

Response in Family Members

It is widely held that drug responses cluster in families. Response to a drug in a relative may predict a patient's response. Although no conclusive evidence supports this as a consideration in drug selection, existing studies do confirm that a history of positive response to treatment with a drug should be considered in making treatment decisions. Of course, certain drugs may not have been available to a family member depending on the era in which they were treated.

Concurrent Medical or Psychiatric Disorders

The initial assessment should elicit information about coexisting medical disorders. In some cases, a medical disorder may be responsible for the symptoms. Patients with thyroid disease who are not adequately treated may appear depressed. Sleep apnea produces depression and cognitive impairment. Rare conditions, such as Kleine–Levin syndrome, can mimic bipolar disorder. A drug should be selected that minimally exacerbates any preexisting medical problems that a particular patient may have.

Recreational drug use, excessive consumption of alcohol, and frequent ingestion of caffeine-containing beverages can complicate and even undermine psychotropic drug treatment. These compounds possess

significant psychoactive properties and, in some cases, may represent the source of the patient's symptoms. It is reasonable to ask patients to abstain from the use of these substances, at least until the benefits of psychotropic drug treatment have been unequivocally established. Gradual reintroduction of moderate amounts of alcohol, tea, and coffee can then take place. Patients can then observe for themselves whether there are any untoward effects on their clinical status.

INFORMED CONSENT AND PATIENT EDUCATION

Establishing trust and motivating the patient to comply with the medication regimen are essential components of successful treatment. Patients should be informed about treatment options and the probable side effects and unique benefits of each treatment. Patient preference should be respected unless a compelling advantage exists involving efficacy, tolerability, or safety with an alternative agent. If a particular medication is being recommended, the reasons for this recommendation should be explained. Patients are more likely to continue taking their medication if they fully understand the reasons why it is being prescribed.

A strong therapeutic alliance between a clinician and a patient is always helpful. Given the unpredictability of medication response, the frequent occurrence of side effects, and underlying ambivalence about, or fear of taking, medication, a constructive, trusting relationship serves to improve patient compliance. Repeated failed trials may be needed before a response is seen. A patient's confidence in the physician's knowledge and judgment enables medication trials and more complex regimens, such as the use of multiple medications.

Discussions about drug selection should be documented in notes, but a signed informed consent is not needed. Surprisingly, patients who are informed of potential adverse effects report a higher incidence of side effects but do not have higher rates of premature discontinuation.

How the patient and family are engaged in the treatment plan can determine the success of treatment. The psychodynamic meaning of pharmacotherapy to the patient and family and environmental influences, psychosocial stressors, and support should be explored. Some patients may view drug treatment as a panacea, and others may view it as the enemy. With

the patient's consent, relatives and other clinicians should be instructed about the reasons for the drug treatment, as well as the expected benefits and potential risks.

DOSING, DURATION, AND MONITORING

Dosing

The clinically effective dose for treatment depends on the characteristics of the drug and patient factors, such as inherited sensitivity and ability to metabolize a drug, concurrent medical disorders, use of concurrent medications, and history of exposure to previous medications.

Plasma concentrations of many psychotropics can vary up to 10-fold. Thus, to some extent, the optimal dose for an individual is ultimately determined by trial and error, guided by the empirical evidence of the usual dose range for that drug. In some cases, it may prove helpful to test patients for genetic polymorphisms involving hepatic enzymes. Patients who are ultrarapid metabolizers of certain drugs may require higher than standard dosing. Slow metabolizers might demonstrate side effects and even toxicity at very low doses.

Some drugs demonstrate a clear relationship between increases in the dose and clinical response. This dose–response curve plots the drug concentration against the effects of the drug.

The *potency* of a drug refers to the relative dose required to achieve specific effects, not to its efficacy. Haloperidol, for example, is more potent than chlorpromazine (Thorazine) because approximately 5 mg of haloperidol is required to achieve the same therapeutic effect as 100 mg of chlorpromazine. These drugs, however, are equal in their clinical efficacy— that is, the maximal clinical response achievable by the administration of a drug.

Drugs must be used in effective dosages for sufficient periods. Although drug tolerability and safety are always considerations, subtherapeutic doses and incomplete therapeutic trials should be avoided. The use of inadequate doses merely exposes the patient to the risk of side effects without providing the probability of therapeutic benefit. Because of the wide margin of safety associated with most currently prescribed medications, more risk exists in

underdosing than in overshooting the recommended dose range.

The time of dosing is usually based on the plasma half-life of a drug and its side effect profile. Sedating drugs are given all at night or with disproportionate daily doses at night. The opposite is true with activating drugs. The frequency of dosing is not as straightforward as with sedating drugs. Most dosing regimens of psychotropic drugs, such as once-a-day versus divided doses, are based on measurements of plasma concentrations rather than receptor occupancy in the brain. Evidence suggests a significant dissociation exists between the brain and plasma kinetics. Reliance on plasma kinetics as the basis for dosing regimens leads to a misunderstanding of necessary schedules.

As a rule, psychotropic drugs should be used continuously. There are some possible exceptions, such as when treating insomnia, agitation, or situational anxiety. A common mistake is the use of high-potency benzodiazepines, such as alprazolam (Xanax) and clonazepam (Klonopin), only after an attack has begun. These drugs should be used as part of a regular schedule to prevent attacks.

Some patients who experience sexual dysfunction while being treated with SSRIs take a drug holiday; that is, they skip a daily dose from time to time to facilitate sexual performance.

Intermittent dosing regimens of SSRIs are effective as a treatment for premenstrual dysphoric disorder (PMDD). The drugs are taken daily during the 2-week luteal phase of the menstrual cycle.

Duration of Treatment

A common question from a patient is, "How long do I need to take the medication?" The answer depends on multiple variables. These include the specific disorder, the symptom duration, and family history. We should also consider the patient's tolerance of and benefit from the medication. Patients can be given a reasonable explanation of the probabilities but should be told that it is first best to see if the medication works for them and whether any side effects are acceptable. Any more definitive discussion of treatment duration can be held once we can assess the degree of success. Even patients with a philosophical aversion to the use of psychotropic drugs may elect to stay on the medication indefinitely if the magnitude of improvement is

excellent. Most psychiatric disorders have high rates of chronicity and relapse. Because of this, long-term treatment is often needed to prevent a recurrence. Nevertheless, the fact remains that psychotropic drugs are not said to cure the disorders they treat but rather to help control the symptoms.

Treatment is conceptually broken down into three phases: the initial therapeutic trial, the continuation, and the maintenance phase. The initial period of treatment should last at least several weeks because of the delay in therapeutic effects that characterize most classes of psychotropic drugs. The required duration of a *therapeutic trial* of a drug should be discussed at the outset of treatment so that the patient does not have unrealistic expectations of an immediate improvement in symptoms. Patients are more likely to experience side effects early in the course of pharmacotherapy than any relief from their disorder. In some cases, medication may even exacerbate some symptoms. Patients should be counseled that a meager initial reaction to medication is not an indicator of the outcome of treatment. For instance, many patients with panic disorder develop jitteriness or an increase in panic attacks after starting on tricyclic or SSRI treatment. Benzodiazepine agonists are an exception to the rule that clinical onset is delayed. In most cases, their hypnotic and antianxiety effects are evident immediately.

Ongoing use of medication, however, does not provide absolute protection against relapse. Continuation therapy provides clinically and statistically significant protective effects against relapse. The optimal duration of continuation or maintenance therapy is variable and dependent on the clinical history of the patient. Early-onset chronic major depression, for example, has a more severe course and more significant comorbidity than late-onset chronic major depression. In addition to early-onset, a history of multiple past episodes and the severity and length of a current episode would suggest that longer, even indefinite, treatment is appropriate.

Frequency of Visits

Until an unequivocal response to treatment occurs, patients should be seen as frequently as circumstances warrant. The frequency of follow-up or monitoring visits is determined by clinical judgment. In severely ill patients, this might mean several times a week. Patients on maintenance therapy, even when stable, need monitoring, but no consensus exists on the frequency of

follow-up therapy. Three months is a reasonable interval between visits, but 6 months may be adequate after long-standing treatment.

LABORATORY TESTS AND THERAPEUTIC BLOOD MONITORING

Laboratory testing and therapeutic blood monitoring should be based on clinical circumstances and the drugs being used. For most commonly used psychotropic drugs, routine testing is not required.

Pretreatment tests are routine as part of a workup to establish baseline values and to rule out underlying medical problems that may be causing the psychiatric symptoms or that might complicate treatment with drugs. Results of recently performed tests should be obtained. With agents known to cause cardiac conduction changes, a pretreatment electrocardiogram (ECG) should be obtained before initiating treatment. With lithium and clozapine, the possibility of severe changes in thyroid, renal, hepatic, or hematologic functions requires pretreatment and ongoing monitoring with appropriate laboratory tests.

As a result of both anecdotal and research findings of sometimes severe glucose dysregulation during treatment primarily with SDAs, the FDA has suggested that patients being treated with any atypical antipsychotic be monitored for the emergence of diabetes.

Certain circumstances present in which it is necessary or useful to use plasma concentrations to monitor a patient's condition. The most common is the monitoring of drugs with narrow therapeutic indexes, such as lithium. Also, we may monitor drugs with a therapeutic window, which is the optimal dose range for a therapeutic response; drug combinations that can lead to interactions that raise drug concentrations of medications or their metabolites, which can cause toxicity; unexplained toxicity at average therapeutic doses; and failure to respond in a patient who may be noncompliant. A clinician should have no reservations about requesting random urine toxicologic tests in a patient who abuses substances.

TREATMENT OUTCOMES

The goal of psychotropic treatment is to eliminate all manifestations of a

disorder, thus enabling the patient to regain the ability to function as well and to enjoy life as fully as before they became ill. This degree of improvement to below the syndromal threshold is defined as *remission*.

Response and Remission

Remission is the preferred outcome of treatment, not only because of the immediate impact on functioning and state of mind but also because emerging evidence suggests that patients in remission are less likely to experience relapse and recurrence of their disorder.

Patients who improve but do not experience a full resolution are considered to be responders. They may exhibit significant improvement but continue to experience symptoms. In depression studies, the *response* is usually defined as a 50 percent or more significant decrease from baseline on a standard rating scale, such as the Hamilton Depression (HAM-D) Scale or the Montgomery-Asberg Depression Rating Scale (MADRS). The scales define r*emission* as an absolute score of 7 or less on the HAM-D or 10 or less on the MADRS.

Our expectations around improvement derive from what we know about the disorder and its response to treatment. Obsessive-compulsive disorder (OCD) and schizophrenia, for example, are more likely to be associated with residual manifestations of illness than major depression or panic disorder. The probability of full remission from OCD with SSRI treatment alone over 2 years is less than 12 percent, and the probability of partial remission is approximately 47 percent.

Treatment Failure

The initial treatment plan should anticipate that the medication may be ineffective. A next-step strategy should be in place at the initiation of treatment. Repeated drug failures should prompt a reassessment of the patient. First, was the original diagnosis correct? In answering this question, the clinician should include the possibility of an undiagnosed medical condition or recreational drug use as the cause of the psychiatric symptoms.

Second, are the observed symptoms related to the original disorder, or are they adverse effects of the drug treatment? Some antipsychotic drugs, for example, can produce akinesia, which resembles psychotic withdrawal, or

akathisia and neuroleptic malignant syndrome, which resemble increased psychotic agitation. Long-term use of SSRIs can produce emotional blunting, which can mimic depression. Intolerance of side effects may be the most common reason for treatment failure.

Third, was the drug administered at an appropriate dosage for a sufficient length of time? Because absorption and metabolism of drugs can vary significantly in patients, the clinician may need to measure plasma levels of a drug to ensure a sufficient dose of the drug.

Fourth, did a pharmacokinetic or pharmacodynamic interaction with another drug that the patient was taking reduce the efficacy of the newly prescribed drug?

Fifth, did the patient take the drug as directed? Drug noncompliance is a common clinical problem that arises as a result of complicated drug regimens (more than one drug in more than one daily dosage), adverse effects (mainly if unnoticed by the clinician), and poor patient education about the drug treatment plan. Patients may discontinue medication when they recover, thinking that they are cured and no longer benefiting from the medication.

Treatment Resistance

Some patients fail to respond to repeated trials of medication. No single factor can explain the ineffectiveness of the various interventions in these cases. Strategies in these cases include the use of drug combinations, high-dose therapy, and the use of unconventional drugs. Limited evidence is available on the comparative success rates associated with any given strategy.

Tolerance

The development of tolerance is marked by a need, over time, to use increased doses of a drug for it to maintain a clinical effect. This decreased responsiveness to a drug occurs after repeated doses. Tolerance also describes decreased sensitivity to adverse effects of the drug, such as nausea. This phenomenon is used as the basis for starting some drugs at subtherapeutic doses, with the plan to adjust the schedule once the patient can tolerate higher doses. Clinical tolerance appears to represent changes in the CNS, such as altered receptor configuration or density. Drugs with similar pharmacologic actions often exhibit cross-tolerance.

Sensitization

Clinically manifested as the reverse of tolerance, sensitization is said to occur when sensitivity to a drug effect increases over time. In these cases, the same dose typically produces more pronounced effects as treatment progresses.

Withdrawal

The development of physiologic adaptation to a drug, with a subsequent risk of withdrawal symptoms, has been reported for many classes of psychotropic drugs. Technically, withdrawal should be considered a side effect. The probability and severity of these reactions are remote with most drugs and more frequent with others. As a general rule, the more abruptly a drug is stopped and the shorter its elimination half-life, the more likely it is that clinically significant withdrawal symptoms will occur. When using some short-acting drugs, withdrawal reactions can result from missed doses and during daily intervals between doses. Gradual tapering of medications after prolonged use is recommended whenever possible. Although this reduces the risk of withdrawal reactions, it does not ensure they will not occur. The so-called sedative-hypnotics and opiates are the agents most often associated with mentally and physically distressing discontinuation reactions. In some cases, such as barbiturate use, withdrawal can be fatal.

Marked differences are found among agents, even within a given class, concerning the probability and severity of discontinuation effects. For example, the benzodiazepines alprazolam and triazolam (Halcion) commonly produce more immediate and intense withdrawal symptoms than other compounds. Among the SSRIs, there is a well-described withdrawal syndrome that appears to be more frequent and severe with paroxetine (Paxil). It can, however, occur with any SSRI. Even fluoxetine can be associated with discontinuation symptoms, but the symptoms may be delayed and attenuated because of the long elimination half-life of its active metabolite. These manifestations are subtle and are delayed for weeks after the last dose. Venlafaxine also produces severe SSRI-like withdrawal syndrome.

In addition to half-life, many variables can influence the likelihood and degree of discontinuation symptoms. Changes in the rate of drug metabolism, as an example, can play a role. Paroxetine is primarily metabolized by the

cytochrome P450 (CYP) 2D6 isoenzyme. However, it is also a potent inhibitor of CYP 2D6. This results in *autoinhibition,* dose-dependent inhibition of its metabolism, with a subsequent increase in plasma concentrations of paroxetine. If the dose of paroxetine is decreased or the drug is stopped, the decline in its plasma concentrations can be steep, causing withdrawal to occur. Withdrawal can occur in rare cases in which the dose of a drug is not decreased, but a second agent, which had been inhibiting its metabolism, was stopped. For example, alprazolam is metabolized via the CYP 3A3/4 enzyme system. Nefazodone inhibits that enzyme. If a patient taking both agents for several weeks discontinues the nefazodone, it could result in a rapid increase in the rate of alprazolam metabolism and a consequent drop in plasma concentrations.

The development of sustained-release versions of drugs, such as alprazolam, paroxetine, and venlafaxine, has not reduced the severity of their withdrawal reactions. The prolonged half-life of those agents results from delayed absorption rather than prolongation of the elimination phase. The frequency of drug dosing is reduced but not the rate of the falloff in plasma concentrations.

Low bioavailability with a generic agent may account for the unexpected loss of clinical effect in the emergence of withdrawal symptoms. The occurrence of these events soon after refilling a prescription should prompt examination of the new medication. It should be confirmed whether the dispensed medication and dose are both correct. It is difficult to ascertain whether generic medications are genuinely equivalent, so the possibility exists that differences in potency may underlie adverse changes in clinical status.

Withdrawal symptoms invariably occur hours or days after dose reduction or discontinuation. Symptoms resolve within a few weeks, so the persistence of symptoms argues against withdrawal. Although depletion studies have been shown to provoke the rapid return of symptoms, in clinical practice, psychotic and mood symptoms do not usually reappear abruptly after long-term treatment.

COMBINATION OF DRUGS

According to the American Psychiatric Association Practice Guidelines for

the Treatment of Psychiatric Disorders, "the use of multiple agents should be avoided if possible" in the treatment of psychiatric disorders. Although *monotherapy* represents the ideal, *polypharmacy,* the simultaneous use of psychotropic medications, has been commonplace since chlorpromazine was combined with reserpine (Diupres) in the early 1950s. The practice of combining drugs and the merits of various *augmentation* or *combination* strategies are routinely discussed in the literature and at scientific meetings. The mean number of simultaneously prescribed medications has increased in recent decades. Among psychiatric inpatients, the mean number of psychotropics prescribed is approximately three. Fixed combinations—drugs that contain more than one active ingredient—have been successfully marketed in the past, and research on new combinations is ongoing. A fluoxetine-olanzapine fixed combination has been approved as a treatment for bipolar disorder. The use of such drugs may increase the patients' compliance by simplifying the drug regimen. A problem with combination drugs, however, is that the clinician has less flexibility in adjusting the dosage of one of the components; that is, the use of combination drugs can cause two drugs to be administered when only one drug continues to be necessary for therapeutic efficacy (Table 21-8).

Table 21-8
Selected Combination Drugs Used in Psychiatry

Ingredients	Preparation	Amount of Each	Recommended Dosage	Indications
Perphenazine and amitriptyline	—	Tablet: 2:25, 4:25, 4:50, 2:10, 4:10	Initial therapy: tablet of 2:25 or 4:25 qid Maintenance therapy: tablet 2:25 or 4:25 bid or qid.	Depression and associated anxiety
Dextroamphetamine and amphetamine	Adderall	Tablet: 5, 7.5, 10.0, 12.5, 15.0, 20.0, 30.0 mg	3–5 yr: 2.5 mg/day; 6 yr and older: 5 mg/day	Attention-deficit/hyperactivity disorder
	Adderall XR	Capsule: 5, 10, 15, 20, 25, 30 mg	—	—
Chlordiazepoxide and clidinium bromide	—	Capsule: 5:25	One or two capsules tid or qid before meals and at bedtime	Peptic ulcer, gastritis, duodenitis, irritable bowel syndrome, spastic colitis, and mild ulcerative colitis
Chlordiazepoxide and amitriptyline	—	Tablet: 5.0:12.5, 10:25	Tablet of 5:12.5 tid or qid; tablet of 10:25 tid or qid, initially, then may increase to six tablets daily as required	Depression and associated anxiety
Olanzapine and fluoxetine	Symbyax	Capsule: 6:25, 6:50, 12:25, 12:50	Once daily in the evening in a dose range of olanzapine 6–12 mg and fluoxetine 25–50 mg	Depressive episodes associated with bipolar I disorder

qid, four times daily; bid, twice daily; tid, three times daily.

Sometimes distinctions are made between augmentation and combination

therapy. When two psychotropics with the same approved indications are used concurrently, this is termed *combination therapy*. Adding a drug with another indication is termed *augmentation*. Augmentation often entails the use of a drug that is not primarily considered a psychotropic. For example, in treating depression, it is not common to add thyroid hormone to an approved antidepressant.

Almost all patients with bipolar disorder are taking more than one psychotropic agent. Combination treatment with drugs that treat depression and DRA or SDA has long been held as preferable in patients with psychotic depression. Similarly, SSRIs typically produce partial improvement in patients with OCD, so the addition of an SDA may be helpful.

Medications also can be combined to counteract side effects, to treat specific symptoms, and as a temporary measure to transition from one drug to another. It is common practice to add a new medication without the discontinuation of a prior drug, mainly when the first drug has provided partial benefit. This addition can be part of a plan to transition from an agent that is not producing a satisfactory response or an attempt to maintain the patient on combined therapy.

The advantages of combining drugs include building on the existing response, which may be less demoralizing, and the possibility that combinations produce new mechanisms that no single agent can provide. One limitation is that noncompliance and adverse effects increase, and the clinician may not be able to determine whether it was the second drug alone or the combination of drugs that resulted in a therapeutic success or a particular adverse effect. Combining drugs can create a broad spectrum effect and also changes the ratio of metabolites.

COMBINED PSYCHOTHERAPY AND PHARMACOTHERAPY

Many psychiatrists believe that patients are best treated with a combination of medication and psychotherapy. Studies have demonstrated that the results of combined therapy are superior to those of either type of therapy alone. When pharmacotherapy and psychotherapy are used together, the approach should be coordinated, integrated, and synergistic. If two separate clinicians direct psychotherapy and pharmacotherapy, the clinicians must communicate with

each other clearly and often.

SPECIAL POPULATIONS

Although every patient brings a unique combination of demographic and clinical variables to the clinical setting, specific patient populations require special consideration. When treating the young, the elderly, those with medical disorders, and women who want to conceive or are pregnant or nursing, awareness of risks associated with medication assumes increased importance. Data derived from clinical trials are of limited value in guiding many decisions because populations in these studies consisted of healthy young adults and, until recently, excluded many women of child-bearing age. Studies of children and adolescents have become more common, so understanding of treatment effects in this population has grown.

Children

Understanding of the safety and efficacy of most psychotropic drugs, when used to treat children, is based more on clinical experience than on evidence from extensive clinical trial data. Often, so results from adult studies are extrapolated to children. This extrapolation is not necessarily appropriate because of developmental differences in pharmacokinetics and pharmacodynamics. Dosing is another special consideration in drug use with children. Although the small volume of distribution suggests the use of lower doses than those used in adults, a child's higher rate of metabolism suggests that a higher ratio of milligrams of a drug to kilograms of body weight should be used. In practice, beginning with a small dose is best, then increasing it until clinical effects are observed. The clinician should not hesitate, however, to use adult dosages in children if these dosages are effective and the adverse effects are acceptable.

The paucity of research data is a legacy of many years in which manufacturers avoided conducting trials in children because of liability concerns, small market share, and, hence, limited profit potential represented by this population. To correct this problem, the FDA Modernization Act (FDAMA) of 1997 provided for special encouragement and incentives to study drugs for pediatric use.

Pregnant and Nursing Women

No definitive assurances exist that any drug is entirely without risk during pregnancy and lactation. No psychotropic medication is absolutely contraindicated during pregnancy, although drugs with known risks of congenital disabilities, premature birth, or neonatal complications should be avoided if acceptable alternatives are available.

Women who are pregnant or lactating are excluded from clinical trials, and it is only recently that women of child-bearing age have been able to participate in these studies. As a result, there are large gaps in knowledge of the effects of psychotropic agents on the developing fetus and the neonate. Most of what is known are the result of anecdotal reports or data from registries. The basic rule is to avoid administering any drug to a woman who is pregnant (particularly during the first trimester) or who is breastfeeding a child unless the mother's psychiatric disorder is severe, and the therapeutic value of the drug outweighs the theoretical adverse effects on the fetus or newborn. A woman may elect to continue on medication because she does not want to chance a possible recurrence of painful or disabling symptoms.

Among the newer antidepressants, paroxetine is the only one to carry a warning from the FDA, the result of an increased risk of cardiac malformation. The agents with the most well-documented risk of specific congenital disabilities are lithium, carbamazepine, and valproate. Lithium administration during pregnancy is associated with Ebstein anomaly, a severe abnormality of cardiac development, although recent evidence suggests that the risk is not as significant as previously believed. Carbamazepine and valproic acid are associated with neural tube defects, which can be prevented by the use of folate during pregnancy. Lamotrigine may cause oral clefts when used during the first trimester. Some experts advise that all women of child-bearing age who are treated with psychotropics take supplemental folate.

The administration of psychotherapeutic drugs at or near delivery can cause the baby to be overly sedated at delivery and require a respirator. They may also be physically dependent on the drug, requiring detoxification and the treatment of a withdrawal syndrome. Reports exist of a neonatal withdrawal syndrome associated with third-trimester use of SSRIs in pregnant women. They have also been implicated in producing pulmonary

hypertension in newborns.

Virtually all psychiatric drugs are secreted in the milk of a nursing mother; therefore, mothers on those agents should be advised not to breastfeed their infants.

Elderly Patients

The two major concerns when treating geriatric patients with psychotherapeutic drugs are that elderly persons may be more susceptible to adverse effects (particularly cardiac effects) and may metabolize and excrete drugs more slowly, thus requiring lower dosages of medication. In practice, clinicians should begin treating geriatric patients with a small dose, usually approximately half of the usual starting dose. The dose should be raised in small increments, more slowly than for middle-aged adults, until a clinical benefit is achieved or unacceptable adverse effects appear. Although many geriatric patients require a small dose of medication, many others require a full therapeutic dose.

Elderly patients account for approximately one-third of all prescription drug use and a substantial percentage of over-the-counter preparations as well. Even more significant is the incidence of polypharmacy. Recent surveys have found that elderly patients in the community are taking between three and five medications, and that hospitalized elderly patients are treated with an average of ten drugs. Nearly half of all patients in long-term care facilities are prescribed one or more psychotropic agents. Because of these statistics, clinicians need to consider potential types and likelihood of drug interactions when selecting medications.

Psychotropic drugs are causally related to falls in the elderly. Discontinuation of psychotropic drugs results in an estimated 40 percent risk reduction for falls. This association between psychotropics and falls and hip fractures may weaken as newer agents become widely used. As a rule, new-generation compounds produce less unwanted sedation, dizziness, parkinsonism, and postural hypotension.

Age-related changes in renal clearance and hepatic metabolism make it more important to be conservative with the starting doses of medication as well as the rate of dose titration. Within any class of psychotropic agents, those with potentially serious consequences, such as hypotension, cardiac

conduction abnormalities, anticholinergic activity, and respiratory depression, are not suitable choices. Drugs that cause cognitive impairment, such as benzodiazepines and anticholinergics, can mimic or exacerbate symptoms of dementia. Similarly, DRAs can worsen or induce Parkinson disease, another age-related disorder. Some side effects, such as SSRI-associated syndrome of inappropriate secretion of antidiuretic hormone (SIADH) and oxcarbazepine-associated hyponatremia, occur more commonly in older patients.

A common ethical dilemma with the medically ill elderly or those with dementia is the question of their capacity to give informed consent before treatment with psychotropic drugs or ECT.

Medically Ill Patients

There are special considerations, diagnostic and therapeutic, when administering psychiatric drugs to medically ill patients. The medical disorder should be ruled out as a cause of psychiatric symptoms. For example, patients with neurologic or endocrine disorders or those infected with human immunodeficiency virus (HIV) may experience disturbances of mood and cognition. Common medications, such as corticosteroids and L-dopa, are associated with the induction of mania.

A patient with diabetes mellitus is better treated with an agent without the risk of weight gain or glucose dysregulation. Depending on the diagnosis, drugs that might treat the primary psychiatric disorder and also cause weight loss, drugs such as bupropion, topiramate, and zonisamide, should be prescribed for these patients. Patients with obstructive pulmonary disease should not be given sedating drugs, which raise the arousal threshold and suppress respiration. Patients with medical disorders are also taking other medications, which can result in pharmacodynamic and pharmacokinetic interactions. Combined treatment with an inducer of multiple CYP enzymes and a drug that is a substrate for those enzymes could result in subtherapeutic levels, leading to inadequate symptom control. The use of the tuberculosis treatment rifampicin (Rifadin) with carbamazepine is an example of this. The use of drugs that inhibit CYP 2D6, agents such as paroxetine and fluoxetine, can prevent the conversion of hydrocodone (Robidone) and other opiates into an active analgesic form. NSAIDs are also a rare cause of perceptual

disturbances and psychotic symptoms.

Other issues include a potentially increased sensitivity to adverse effects, including increased or decreased metabolism and excretion of the drug, and interactions with other medications. Drug interactions are an obvious concern when drugs with a narrow therapeutic range are being used. Any change in the rate of metabolism or interference with the formation and elimination of metabolites can profoundly influence the activity of that drug. Similarly, interactions that interfere with drug metabolism can produce an increase in side effects and toxicity.

As with children and geriatric patients, the most reasonable clinical practice is to begin with a small dosage, to increase it slowly, and to watch for clinical benefit and adverse effects. Determining the plasma drug concentrations may be helpful for such patients, but therapeutic blood concentrations for most psychotropic drugs are neither necessary nor routinely available.

Substance Abuse

Many patients who seek or need treatment for a psychiatric disorder chronically use illicit substances or drink excessive amounts of alcohol. Discontinuation of chronic drug or alcohol use can result not only in craving but also in clinically significant psychiatric and physiologic withdrawal symptoms. For many patients, successful treatment of their underlying psychiatric disorder may not be possible in the presence of ongoing marijuana, cocaine, and alcohol use. If several trials of medications fail, hospitalization for detoxification may be necessary. Little research and no consensus exist about how to use psychotropic agents in patients who are regular users of cocaine, marijuana, or other recreational drugs.

REGULATORY ISSUES

The FDA has the authority to approve a drug for clinical use and to ensure that product labeling is truthful and contains all information pertinent to the safe and effective use of that drug.

Product information that is FDA approved for marketed drugs appears as a package insert that lists potential side effects, drug interactions, the need for special monitoring, and restrictions for use. In some cases, these adverse

reactions and potential safety hazards warrant a warning label called a *black box label*. The FDA typically negotiates final labeling language with the company; however, in cases where a company refuses to satisfy the FDA, the agency may initiate proceedings to remove the drug from clinical use. In recent years, warning labels have been applied to entire classes of psychotropic drugs, including the SDAs and antidepressants such as the SSRIs.

The product information may also contain a "Contraindications" heading. This section describes instances in which the drug should not be used because the risk of using it outweighs the benefit. If no contraindications are known, this section of the labeling will state "None known."

A Precautions section may contain precautions for most individuals taking the drug, as well as for specific groups, such as pregnant women, nursing mothers, or children. In this section, one will find recommendations for patients to ensure the safe and effective use of the drug. For example, there may be precautions about driving when taking the medication or using substances such as other drugs, food, or alcohol that may have harmful effects if taken while using the medication. The precautions section also provides information about laboratory tests needed to track responses or to identify adverse reactions to the drug or about known interactions with other drugs, foods, or ingredients.

Every product label has an Adverse Reaction section that lists the frequency of undesirable effects that may be associated with the use of a drug. Causes of adverse reactions can include medication errors, such as overdosage, or interactions between different drugs or between drugs and certain foods.

NONAPPROVED DOSAGES AND USES

It is now common practice to treat psychiatric disorders with drugs that are approved for nonpsychiatric conditions. Some examples include propranolol (Inderal) for social anxiety and treatment of lithium-induced tremor; verapamil (Calan, Isoptin) for mania and treatment of MAOI-induced hypertensive crisis; levothyroxine (Levoxyl) for antidepressant augmentation; clonidine (Catapres) and guanfacine (Tenex) for posttraumatic stress disorder (PTSD); dextroamphetamine (Dexedrine) for antidepressant augmentation;

and riluzole (Rilutek) for self-injurious behavior. Off-label use of a drug is not a violation of law or a departure from good medical practice. The FDA does not limit how a physician may use an approved drug. Medications can be prescribed for any reason shown to be medically indicated for the welfare of the patient. Once a drug is approved for commercial use, a physician can, as part of the practice of medicine, lawfully prescribe a different dosage for a patient or may otherwise vary the conditions of use from what is approved in the package labeling without notifying the FDA or obtaining its approval.

Failure to follow the information on the drug label does not in itself impose liability and should not preclude a physician from using sound clinical judgment in the service of the patient. Physicians are permitted to use a drug for indications not included on the drug's official labeling without violating the FDA rules. This fact, however, does not absolve the physician of responsibility for an untoward result from treatment. Patients can still sue for possible medical malpractice with the reasoning that the failure to follow the FDA-approved label can be interpreted as deviating from the prevailing standard of care.

When using a drug off-label or in doses outside the usual range, we should explain to the patient the reasons for this approach. We should also document it in the chart. When doubting the plan to use a drug off label, a consultation with a colleague should be obtained.

In some cases, a drug has obtained limited approval for an indication. Divalproex (Depakote) and risperidone, for example, are approved by the FDA for the acute, but not long-term, treatment of mania. Nevertheless, these drugs are routinely used for long-term prevention of recurrences of mania and bipolar disorder. In the case of lamotrigine, it was accepted as a first-choice agent for the treatment of bipolar disorder long before the FDA approved that indication.

PLACEBOS

Pharmacologically inactive substances have long been known sometimes to produce significant clinical benefits. A patient who believes that a compound is helpful may often derive considerable benefit from taking that substance, whether it is known to be pharmacologically active or not. For many psychiatric disorders, including mild to moderate depression and some

anxiety disorders, well over 30 percent of patients can exhibit significant improvement or remission of symptoms on a placebo. For other conditions, such as schizophrenia, manic episodes, and psychotic depression, the placebo response rate is meager. Whereas suggestion is undoubtedly crucial in the efficacy of placebos (and active drugs), placebos can produce biologic effects. For example, placebo-induced analgesia may sometimes be blocked by naloxone (Narcan), which suggests that endorphins may mediate the analgesia derived from taking a placebo. It is conceivable that placebos may also stimulate endogenous anxiolytic and antidepressant factors, resulting in clinical improvement in patients with depression and anxiety disorders.

Just as placebos can produce benefits, they can also have adverse effects. In many studies, some adverse effects are likely to be more frequent with placebos than with the active drug. Some patients will not tolerate placebos, although they are supposedly inert, and they exhibit adverse effects (called the *nocebo phenomenon*). It is easy to discount such patients as overly suggestible; however, if placebos can stimulate beneficial endogenous factors, perhaps toxic endogenous factors can also be produced.

Prudence is needed in contemplating the use of a placebo in clinical practice. Treating a patient with a placebo without consent can seriously undermine a patient's confidence in the physician if, and when, it is discovered.

▲ 21.1 Antipsychotics

SEROTONIN–DOPAMINE ANTAGONISTS AND SIMILARLY ACTING DRUGS (SECOND-GENERATION OR ATYPICAL ANTIPSYCHOTICS)

The SGAs, also known as second-generation or atypical antipsychotic drugs, are a group of pharmacologically diverse drugs that have largely supplanted the older DRAs. The term *atypical* is used because these drugs differ in their side effect profiles, most notably lower risk of extrapyramidal side effects (EPS), and have spectra of action that are broader than those of the DRAs. However, this term is becoming something of a misnomer, as the drugs are

now more commonly used than the "typical" antipsychotics. In contrast to the earlier antipsychotic drugs, the SGAs have significant effects on both the dopamine and serotonin systems. Their pharmacology is complex, with individual drugs in this group having multiple neurotransmitter effects. All SGAs are indicated for the treatment of schizophrenia. Most of these SGA drugs have also received approval as monotherapy or adjunctive therapy in the treatment of bipolar disorder. Some have also been approved as adjuncts for the treatment of major depression.

As of 2020, 13 SGA drugs were approved by the FDA. These include the following:

Aripiprazole (marketed as Abilify)
Asenapine Maleate (marketed as Saphris)
Brexpiprazole (marketed as Rexulti)
Cariprazine (marketed as Vraylar)
Clozapine (marketed as Clozaril)
Iloperidone (marketed as Fanapt)
Lumateperone (marketed as Caplyta)
Lurasidone (marketed as Latuda)
Olanzapine (marketed as Zyprexa, and as Symbyax in combination with
    fluoxetine)
Paliperidone (marketed as Invega)
Quetiapine (marketed as Seroquel)
Risperidone (marketed as Risperdal)
Ziprasidone (marketed as Geodon)

It is arguable whether the SGAs represent an improvement in overall tolerability than the DRAs. Although there is an improvement concerning a lowered, not absent, risk of EPS, most of the drugs in this group often produce substantial weight gain, which in turn increases the potential for the development of diabetes mellitus. Olanzapine and clozapine appear to account for most cases of weight gain and drug-induced diabetes mellitus. The other agents pose a smaller risk of these side effects; nevertheless, the FDA has requested that all SGAs carry a warning label that patients taking the drugs need to be monitored closely, and has recommended the following factors be considered for all patients prescribed SGAs:

1. Personal and family history of obesity, diabetes, dyslipidemia, hypertension, and cardiovascular disease
2. Weight and height (so that body mass index can be calculated)
3. Waist circumference (at the level of the umbilicus)
4. BP
5. Fasting plasma glucose level
6. Fasting lipid profile

Patients with preexisting diabetes should have regular monitoring, including hemoglobin A1C (HbA1C) and, in some cases, insulin levels. Among these drugs, clozapine sits apart. It is not considered a first-line agent because of side effects (hematologic) and the need for weekly blood tests. Although highly effective in treating both mania and depression, clozapine does not have an FDA indication for these conditions.

Mechanisms of Action

The presumed antipsychotic effects of the SDAs are blockade of D_2 dopamine receptors. Where the SDAs differ from older antipsychotic drugs is their higher ratio interactions with serotonin receptor subtypes, most notably the 5-HT_{2A} subtype, as well as with other neurotransmitter systems. It is hypothesized that these properties account for the distinct tolerability profiles associated with each of the SDAs. All SDAs have different chemical structures, receptor affinities, and side effect profiles. No SDA is identical in its combination of receptor affinities, and the relative contribution of each receptor interaction to the clinical effects is unknown.

Therapeutic Indications

Although initially approved for the treatment of schizophrenia and acute mania, some of these drugs have also been approved as adjunctive therapy in treatment-resistant depression and as adjunctive therapy in major depressive disorder (MDD). They are also useful in PTSD and anxiety disorders. Although clinicians tend to use them in behavioral disturbances associated with dementia, all SDAs carry an FDA boxed warning regarding adverse effects when used in elderly persons with dementia-related psychoses, because elderly patients with dementia-related psychoses are at an increased

risk (1.6 to 1.7 times) of death compared with placebo. All of these agents are considered first-line drugs for schizophrenia except clozapine, which may cause adverse hematologic effects that require weekly blood sampling.

Schizophrenia and Schizoaffective Disorder. The SDAs are useful for treating acute and chronic psychoses such as schizophrenia and schizoaffective disorder, in both adults and adolescents. SDAs are as good as or better than typical antipsychotics (DRAs) for the treatment of positive symptoms in schizophrenia and superior to DRAs for the treatment of negative symptoms. Compared with persons treated with DRAs, persons treated with SDAs have fewer relapses and require less frequent hospitalization, fewer emergency department visits, less phone contact with mental health professionals, and less treatment in day programs.

Because clozapine has potentially life-threatening adverse effects, it is appropriate only for patients with schizophrenia who are resistant to all other antipsychotics. Other indications for clozapine include treatment of persons with severe tardive dyskinesia—which can be reversed with high dosages in some cases—and those with a low threshold for EPS. Persons who tolerate clozapine have done well on long-term therapy. The effectiveness of clozapine may be increased by augmentation with risperidone, which raises clozapine concentrations and sometimes results in dramatic clinical improvement.

Mood Disorders. Most of the SDAs (clozapine being a notable exception) are FDA approved for the treatment of acute mania. Some of these agents, including aripiprazole, olanzapine, quetiapine, and quetiapine XR, are also approved for the maintenance treatment in bipolar disorder as monotherapy or adjunctive therapy. The SDAs improve depressive symptoms in schizophrenia, and both clinical experience and clinical trials show that all of the SDAs augment antidepressants in the acute management of major depression. At this time, olanzapine, in combination with fluoxetine, has been approved for treatment-resistant depression, and aripiprazole and quetiapine XR are indicated for adjunctive therapy to antidepressants in MDDs. Quetiapine and quetiapine XR are also approved in bipolar depression. A fixed combination of olanzapine and fluoxetine (Symbyax) is approved as a treatment for acute bipolar depression.

Other Indications. About 10 percent of patients with schizophrenia exhibit outwardly aggressive or violent behavior, and the SDAs are effective for the treatment of such aggression. Other off-label indications include acquired immunodeficiency syndrome (AIDS) dementia, autism spectrum disorders, Tourette disorder, Huntington disease, and Lesch–Nyhan syndrome. Risperidone and olanzapine have been used to control aggression and self-injury in children. These drugs are sometimes coadministered with stimulants to children with ADHD who are comorbid for either oppositional–

defiant disorder or conduct disorder. SDAs—especially olanzapine, quetiapine, and clozapine—are useful in persons who have severe tardive dyskinesia. The SDAs are also effective for treating psychotic depression and for psychosis secondary to head trauma, dementia, or treatment drugs.

Treatment with SDAs decreases the risk of suicide and water intoxication in patients with schizophrenia. Patients with treatment-resistant OCD have responded to the SDAs; however, a few persons treated with the SDAs have been noted to develop treatment-emergent symptoms of OCD. Some patients with borderline personality disorder may improve with the SDAs.

Some data suggest that treatment with conventional DRAs has protective effects against the progression of schizophrenia when used during the first episode of psychosis. Ongoing studies are looking at whether the use of SDAs in at-risk patients with early evidence of disease prevents deterioration, thus improving long-term outcomes.

Adverse Effects

The SDAs share a similar spectrum of adverse reactions but differ considerably in terms of frequency or severity of their occurrence. Specific side effects that are more common with an individual SDA are emphasized in the discussion of each drug in subsequent text.

Risperidone (Risperdal)

Indications. Risperidone is indicated for the acute and maintenance treatment of schizophrenia in adults and the treatment of schizophrenia in adolescents ages 13 to 17 years. Risperidone is also indicated for the short-term treatment of acute manic or mixed episodes associated with bipolar I disorder in adults and children and adolescents ages 10 to 17 years. The

combination of risperidone with lithium or valproate is indicated for the short-term treatment of acute manic or mixed episodes associated with bipolar I disorder.

Risperidone is also indicated for the treatment of irritability associated with an autistic spectrum disorder in children and adolescents ages 5 to 16 years, including symptoms of aggression toward others, deliberate self-injuriousness, temper tantrums, and quickly changing moods.

Pharmacology. Risperidone is a benzisoxazole. It undergoes extensive first-pass hepatic metabolism to 9-hydroxy risperidone, a metabolite with equivalent antipsychotic activity. Peak plasma levels of the parent compound occur within 1 hour for the parent compound and 3 hours for the metabolite. Risperidone has bioactivity of 70 percent. The combined half-life of risperidone and 9-hydroxy risperidone averages 20 hours, so it is useful in once-daily dosing. Risperidone is an antagonist of the serotonin 5-HT_{2A}, dopamine D_2, α_1-adrenergic and α_2-adrenergic, and histamine H_1 receptors. It has a low affinity for α-adrenergic and muscarinic cholinergic receptors. Risperidone is a potent antagonist of D_2 receptors, as potent as haloperidol, however unlike haloperidol it causes less EPS.

Dosages. The recommended dose range and frequency of risperidone dosing have changed since the drug first came into clinical use. Risperidone is available in 0.25-, 0.5-, 1-, 2-, 3-, and 4-mg tablets and a 1-mg/mL oral solution. The initial dosage is usually 1 to 2 mg at night, which can then be increased to 4 mg/day. Positron emission tomography (PET) studies have shown that dosages of 1 to 4 mg/day provide the required D_2 blockade for a therapeutic effect. At first, it was believed that because of its short elimination half-life, risperidone should be given twice a day, but studies have shown equal efficacy with once-a-day dosing. Dosages above 6 mg a day are associated with a higher incidence of adverse effects, particularly EPS. There is no correlation between plasma concentrations and therapeutic effects. Dosing guidelines for adolescents and children are different from those for adults, requiring lower starting dosages; higher dosages are associated with more adverse effects.

Side Effects. The EPS of risperidone is largely dosage dependent, and there has been a trend to using lower doses than initially recommended. Weight gain, anxiety, nausea and vomiting, rhinitis, erectile dysfunction, orgasmic dysfunction, and increased pigmentation are associated with risperidone use. The most common drug-related reasons for discontinuation of risperidone use are EPS, dizziness, hyperkinesias, somnolence, and nausea. Marked elevation of prolactin may occur. Weight gain occurs more commonly with risperidone use in children than in adults.

Risperidone is also available as an orally disintegrating tablet (Risperdal M-Tab), which is available in 0.5, 1, and 2 mg strengths, and in a depot formulation (Risperdal Consta), which is given as an intramuscular (IM) injection formulation every 2 weeks. The dose may be 25, 50, or 75 mg. Oral risperidone should be coadministered with Risperdal Consta for the first 3 weeks before being discontinued.

Drug Interactions. Inhibition of CYP2D6 by drugs such as paroxetine and fluoxetine can block the formation of risperidone's active metabolite. Risperidone is a weak inhibitor of CYP2D6 and has little effect on other drugs. Combined use of risperidone and SSRIs may result in significant elevation of prolactin, with associated galactorrhea and breast enlargement.

Paliperidone (Invega)

Indications. Paliperidone is indicated for the acute and maintenance treatment of schizophrenia. Paliperidone is also indicated for the acute treatment of schizoaffective disorder as monotherapy or as an adjunct to mood stabilizers or antidepressants.

Pharmacology. Paliperidone is a benzisoxazole derivative and is the primary active metabolite of risperidone. Peak plasma concentrations (C_{max}) are achieved approximately 24 hours after dosing, and steady-state concentrations of paliperidone are attained within 4 or 5 days. The hepatic isoenzymes CYP2D6 and CYP3A4 play a limited role in the metabolism and elimination of paliperidone, so no dose adjustment is required in patients with mild or moderate hepatic impairment.

Dosage. Paliperidone is available in 3-, 6-, and 9-mg tablets. The recommended dosage is 6 mg once daily administered in the morning. It can be taken with or without food. It is also available as extended-release tablets, which are also available in 3-, 6-, and 9-mg tablets administered once daily. It is recommended that no more than 12 mg should be administered per day. A long-acting formulation of paliperidone (Invega Sustenna) is given by injection once a month. Invega Sustenna is available as a white to off-white sterile aqueous extended-release suspension for intramuscular injection in dose strengths of 39-, 78-, 117-, 156-, and 234-mg paliperidone palmitate. The drug product hydrolyzes to the active moiety, paliperidone, resulting in dose strengths of 25, 50, 75, 100, and 150 mg of paliperidone, respectively.

Invega Sustenna is provided in a prefilled syringe with a plunger stopper and tip cap. The kit also contains two safety needles (a 1½-in 22-gauge safety needle and a 1-in 23-gauge safety needle). It has a half-life of 25 to 49 days. Monthly injections of 117 mg are recommended, although higher or lower dosages can be used depending on the clinical situation. The first two injections should be in the deltoid muscle because plasma concentrations are 28 percent higher with deltoid versus gluteal administration. Subsequent injections can alternate between gluteal and deltoid sites.

Side Effects. The dose of paliperidone should be reduced in patients with renal impairment. It may cause more sensitivity to temperature extremes, such as very hot or cold conditions. Paliperidone may cause an increase in QT (QTc) interval and should be avoided in combination with other drugs that cause prolongation of QT interval. It may cause orthostatic hypotension, tachycardia, somnolence, akathisia, dystonia, EPS, and parkinsonism.

Olanzapine (Zyprexa)

Indications. Olanzapine is indicated for the treatment of schizophrenia. Oral olanzapine is indicated for use as monotherapy for the acute treatment of manic or mixed episodes associated with bipolar I disorder and maintenance treatment of bipolar I disorder. Oral olanzapine is also indicated for the treatment of manic or mixed episodes associated with bipolar I disorder as an adjunct to lithium or valproate, and olanzapine can also be used in combination with fluoxetine (Symbyax) for the treatment of depressive

episodes associated with bipolar I disorder.

Oral olanzapine and fluoxetine in combination (Symbyax) is indicated for the treatment of treatment-resistant depression. Olanzapine monotherapy is not indicated for the treatment of treatment-resistant depression.

Pharmacology. Approximately 85 percent of olanzapine is absorbed from the GI tract, and about 40 percent of the dosage is inactivated by first-pass hepatic metabolism. Peak concentrations are reached in 5 hours, and the half-life averages 31 hours (range 21 to 54 hours). It is given in once-daily dosing. In addition to 5-HT_{2A} and D_2 antagonism, olanzapine is an antagonist of the D_1, D_4, α_1, 5-HT_{1A}, muscarinic M_1 to M_5, and H_1 receptors.

Dosages. Olanzapine is available in 2.5-, 5-, 7.5-, 10-, 15-, and 20-mg oral and Zydis form (orally disintegrating) tablets. The initial dosage for the treatment of psychosis is usually 5 or 10 mg. For acute mania, it is usually 10 or 15 mg given once daily. It is also available as 5-, 10-, 15-, and 20-mg orally disintegrating tablets that might be useful for patients who have difficulty swallowing pills or who "cheek" their medication.

A starting daily dose of 5 to 10 mg is recommended. After 1 week, the dosage can be raised to 10 mg a day. Given the long half-life, 1 week must be allowed to achieve each new steady-state blood level. Dosages in clinical use ranges vary, with 5 to 20 mg a day is most commonly used, but 30 to 40 mg a day is needed in treatment-resistant patients. A word of caution, however, is that the higher dosages are associated with increased EPS and other adverse effects, and dosages above 20 mg a day were not studied in the pivotal trials that led to the approval of olanzapine. The parenteral form of olanzapine is indicated for the treatment of acute agitation associated with schizophrenia and bipolar disorder, and the IM dosage is 10 mg. Coadministration with benzodiazepines is not approved.

Other Formulations. Olanzapine is available as an extended-release injectable suspension (Relprevv), which is a long-acting atypical IM injection indicated for the treatment of schizophrenia. It is injected deep in the gluteal region and should not be administered intravenously or subcutaneously, nor is it approved for deltoid administration. Before administering the injection, the administrator should aspirate the syringe for several seconds to ensure

that no blood is visible. It carries a boxed warning for postinjection delirium sedation syndrome (PDSS). Patients are at risk for severe sedation (including coma) and must be observed for 3 hours after each injection in a registered facility. In controlled studies, all patients with PDSS recovered, and there were no deaths reported. It is postulated that PDSS is secondary to increased levels of olanzapine secondary to accidental rupture of a blood vessel, causing extreme sedation or delirium. Patients should be managed as clinically appropriate and, if necessary, monitored in a facility capable of resuscitation. The injection can be given every 2 or 4 weeks, depending on the dosing guidelines.

Drug Interactions. Fluvoxamine (Luvox) and cimetidine (Tagamet) increase, and carbamazepine and phenytoin decrease, serum concentrations of olanzapine. Ethanol increases olanzapine absorption by more than 25 percent, leading to increased sedation. Olanzapine has little effect on the metabolism of other drugs.

Side Effects. Other than clozapine, olanzapine consistently causes a more significant amount and more frequent weight gain than other atypicals. This effect is not dose-related and continues over time. Clinical trial data suggest it peaks after 9 months, after which it may continue to increase more slowly. Somnolence, dry mouth, dizziness, constipation, dyspepsia, increased appetite, akathisia, and tremor are associated with olanzapine use. A small number of patients (2 percent) may need to discontinue the use of the drug because of transaminase elevation. There is a dose-related risk of EPS. The manufacturer recommends a "periodic" assessment of blood sugar and transaminases during treatment with olanzapine. There is an FDA-mandated warning about an increased risk of stroke among patients with dementia treated with SDAs, but this risk is small and is outweighed by improved behavioral control that treatment may produce.

Quetiapine (Seroquel)

Indications. Quetiapine is indicated for the treatment of schizophrenia. It is also indicated for the acute treatment of manic episodes associated with bipolar I disorder, both as monotherapy and as an adjunct to lithium or

sodium valproate. It is also indicated as monotherapy for the acute treatment of depressive episodes associated with bipolar disorder and maintenance treatment of bipolar I disorder as an adjunct to lithium or divalproex. It also is indicated as adjunctive therapy to antidepressants for the treatment of MDD.

Pharmacology. Quetiapine is a dibenzothiazepine structurally related to clozapine, but it differs markedly from that agent in biochemical effects. It is rapidly absorbed from the GI tract, with peak plasma concentrations reached in 1 to 2 hours. The steady-state half-life is about 7 hours, and optimal dosing is two or three times per day. Quetiapine, in addition to being an antagonist of D_2 and 5-HT_2, also blocks 5-HT_6, D_1 and H_1, and α_1 and α_2 receptors. It does not block muscarinic or benzodiazepine receptors. The receptor antagonism for quetiapine is generally lower than that for other antipsychotic drugs, and it is not associated with EPS.

Dosages. Quetiapine is available in 25-, 50-, 100-, 200-, 300-, and 400-mg tablets. Quetiapine dosing should begin at 25 mg twice daily, with doses then increased by 25 to 50 mg/dose every 2 to 3 days, up to a target of 300 to 400 mg a day. Studies have shown efficacy in the range of 300 to 800 mg a day. In reality, more aggressive dosing is both tolerated and more effective. It has become evident that the target dose can be achieved more rapidly and that some patients benefit from dosages of as much as 1,200 to 1,600 mg a day. When used at higher doses, serial ECG studies are required. Despite its short elimination half-life, quetiapine can be given to many patients once a day. This dosing is consistent with the observation that quetiapine receptor occupancy remains even when concentrations in the blood have markedly declined. Quetiapine in doses of 25 to 300 mg at night has been used for insomnia.

Other Formulations. Quetiapine XR has comparable bioavailability to an equivalent dose of quetiapine administered two or three times daily. Quetiapine XR is given once daily, preferably in the evening, 3 to 4 hours before bedtime without food or a light meal to prevent an increase in C_{max}. The usual starting dose is 300 mg, and it may be increased to 400 to 800 mg.

Drug Interactions. The potential interactions between quetiapine and other

drugs have been well studied. Phenytoin increases quetiapine clearance fivefold; no significant pharmacokinetic interactions have been noted. Avoid the use of quetiapine with drugs that increase the QT interval and in patients with risk factors for prolonged QT interval. The FDA has added a new warning about quetiapine, cautioning prescribers about potential prolongation of the QT interval when above-recommended amounts of quetiapine are combined with specific drugs. Quetiapine should not be combined with other drugs that are known to prolong QTc. This includes class 1A antiarrhythmics (e.g., quinidine, procainamide) or class III antiarrhythmics (e.g., amiodarone, sotalol), antipsychotic medications (e.g., ziprasidone, chlorpromazine, thioridazine), antibiotics (e.g., gatifloxacin, moxifloxacin), or any other class of medications known to prolong the QTc interval (e.g., pentamidine, levomethadyl acetate, methadone). Quetiapine should also be avoided in circumstances that may increase the risk of occurrence of torsade de pointes or sudden death, including (1) a history of cardiac arrhythmias such as bradycardia; (2) hypokalemia or hypomagnesemia; (3) concomitant use of other drugs that prolong the QTc interval; and (4) presence of congenital prolongation of the QT interval. Postmarketing cases also show increases in QT interval in patients who overdose on quetiapine.

Side Effects. Somnolence, postural hypotension, and dizziness are the most common adverse effects of quetiapine. These are usually transient and are best managed with initial gradual upward titration of the dosage. Quetiapine is the SDA least likely to cause EPS, regardless of dose. This makes it particularly useful in treating patients with Parkinson disease who develop dopamine agonist-induced psychosis. Prolactin elevation is rare and both transient and mild when it occurs. Quetiapine is associated with modest transient weight gain in some persons, but some patients occasionally gain a considerable amount of weight. The relationship between quetiapine and the development of diabetes is not as clearly established as are the cases involving the use of olanzapine. Small increases in heart rate, constipation, and a transient increase in liver transaminases may also occur. Initial concerns about cataract formation, based on animal studies, have not been borne out since the drug has been in clinical use. Nevertheless, it might be prudent to test for lens abnormalities early in treatment and periodically after that.

Ziprasidone (Geodon)

Indications. Ziprasidone is indicated for the treatment of schizophrenia. Ziprasidone is also indicated as monotherapy for the acute treatment of manic or mixed episodes associated with bipolar I disorder and as an adjunct to lithium or valproate for the maintenance treatment of bipolar I disorder.

Pharmacology. Ziprasidone is a benzisothiazole piperazine. Peak plasma concentrations of ziprasidone are reached in 2 to 6 hours. Steady-state levels ranging from 5 to 10 hours are reached between the first and the third days of treatment. The mean terminal half-life at steady state ranges from 5 to 10 hours, which accounts for the recommendation that twice-daily dosing is necessary. Bioavailability doubles when ziprasidone is taken with food, and therefore it should be taken with food.

Peak serum concentrations of IM ziprasidone occur after approximately 1 hour, with a half-life of 2 to 5 hours.

Ziprasidone, similar to the other SDAs, blocks 5-HT_{2A} and D_2 receptors. It is also an antagonist of 5-HT_{1D}, 5-HT_{2C}, D_3, D_4, α_1, and H_1 receptors. It has a very low affinity for D_1, M_1, and α_2 receptors. Also, ziprasidone has agonist activity at the serotonin 5-HT_{1A} receptors and is an SSRI and a norepinephrine reuptake inhibitor. This action is consistent with clinical reports that ziprasidone has antidepressant-like effects in nonschizophrenic patients.

Dosages. Ziprasidone is available in 20-, 40-, 60-, and 80-mg capsules. Ziprasidone for IM use comes as a single-use 20 mg/mL vial. Oral ziprasidone dosing should be initiated at 40 mg a day, divided into two daily doses. Studies have shown efficacy in the range of 80 to 160 mg a day, divided twice daily. In clinical practice, doses as high as 240 mg a day are being used. The recommended IM dosage is 10 to 20 mg every 2 hours for the 10-mg dose and every 4 hours for the 20-mg dose. The maximum total daily dose of IM ziprasidone is 40 mg.

Other than interactions with other drugs that prolong the QTc complex, ziprasidone appears to have a low potential for clinically significant drug interactions.

Side Effects. Somnolence, headache, dizziness, nausea, and lightheadedness are the most common adverse effects in patients taking ziprasidone. The drug has almost no significant effects outside the CNS, is associated with almost no weight gain, and does not cause sustained prolactin elevation. Concerns about prolongation of the QTc complex have deterred some clinicians from using ziprasidone as a first choice. The QTc interval has been shown to increase in patients treated with 40 and 120 mg/day. Ziprasidone is contraindicated in combination with other drugs known to prolong the QTc interval. These include, but are not limited to, dofetilide, sotalol, quinidine, other class IA and III antiarrhythmics, mesoridazine, thioridazine, chlorpromazine, droperidol, pimozide, sparfloxacin, gatifloxacin, moxifloxacin, halofantrine, mefloquine, pentamidine, arsenic trioxide, levomethadyl acetate, dolasetron mesylate, probucol, and tacrolimus. Ziprasidone should be avoided in patients with congenital long QT syndrome and patients with a history of cardiac arrhythmias.

Aripiprazole (Abilify)

Aripiprazole is a potent 5-HT_{2A} antagonist and is indicated for the treatment of both schizophrenia and acute mania. It is also approved for the augmentation of antidepressant agents in MDD. Aripiprazole is a D_2 antagonist, but can also act as a partial D_2 agonist. Partial D_2 agonists compete at D_2 receptors for endogenous dopamine, thereby producing a functional reduction of dopamine activity.

Indications. Aripiprazole is indicated for the treatment of schizophrenia. Short-term, 4- to 6-week studies comparing aripiprazole with haloperidol and risperidone in patients with schizophrenia and schizoaffective disorder have shown comparable efficacy. Dosages of 15, 20, and 30 mg a day were found to be effective. Long-term studies suggest that aripiprazole is effective as a maintenance treatment at a daily dose of 15 to 30 mg.

Aripiprazole is also indicated for the acute and maintenance treatment of manic and mixed episodes associated with bipolar I disorder. It is also used as adjunctive therapy to either lithium or valproate for the acute treatment of manic and mixed episodes associated with bipolar I disorder.

Aripiprazole is indicated for use as adjunctive therapy to antidepressants

for the treatment of MDD. Aripiprazole is also indicated for the treatment of irritability associated with autistic disorder.

Pharmacology. Aripiprazole is well absorbed, reaching peak plasma concentrations after 3 to 5 hours. Absorption is not affected by food. The mean elimination half-life of aripiprazole is about 75 hours. It has a weakly active metabolite with a half-life of 96 hours. These relatively long half-lives make aripiprazole suitable for once-daily dosing. Clearance is reduced in elderly persons. Aripiprazole exhibits linear pharmacokinetics and is primarily metabolized by CYP3A4 and CYP2D6 enzymes. It is 99 percent protein-bound. Aripiprazole is excreted in breast milk in lactating rats.

Mechanistically, aripiprazole acts as a modulator, rather than a blocker, and acts on both postsynaptic D_2 receptors and presynaptic autoreceptors. In theory, this mechanism addresses excessive limbic dopamine (hyperdopaminergic) activity and decreased dopamine (hypodopaminergic) activity in frontal and prefrontal areas—abnormalities that are thought to be present in schizophrenia. The absence of a complete D_2 blockade in the striatal areas would be expected to minimize EPS. Aripiprazole is an α_1-adrenergic receptor antagonist, which may cause some patients to experience orthostatic hypotension. Similar to the so-called atypical antipsychotic agents, aripiprazole is a 5-HT_{2A} antagonist.

Other Uses. A study of aggressive children and adolescents with oppositional defiant disorder or conduct disorder found that there was a positive response in about 60 percent of the subjects. In this study, vomiting and somnolence led to a reduction in initial aripiprazole dosage.

Drug Interactions. Whereas carbamazepine and valproate reduce serum concentrations, ketoconazole, fluoxetine, paroxetine, and quinidine increase aripiprazole serum concentrations. Lithium and valproic acid, two drugs likely to be combined with aripiprazole when treating bipolar disorder, do not affect the steady-state concentrations of aripiprazole. Combined use with antihypertensives may cause hypotension. Drugs that inhibit CYP2D6 activity reduce aripiprazole elimination.

Dosage and Clinical Guidelines. Aripiprazole is available as 5-, 10-, 15-

, 20-, and 30-mg tablets. The effective dosage range is 10 to 30 mg/day. Although the starting dosage is 10 to 15 mg/day, problems with nausea, insomnia, and akathisia have led to the use of lower than recommended starting dosages of aripiprazole. Many clinicians find that an initial dose of 5 mg increases tolerability.

Side Effects. The most commonly reported side effects of aripiprazole are headache, somnolence, agitation, dyspepsia, anxiety, and nausea. Although it is not a frequent cause of EPS, aripiprazole does cause akathisia-like activation. Described as restlessness or agitation, it can be highly distressing and often leads to discontinuation of the medication. Insomnia is another common complaint. Data so far do not indicate that weight gain or diabetes mellitus have an increased incidence with aripiprazole. Prolactin elevation does not typically occur. Aripiprazole does not cause significant QTc interval changes. There have been reports of seizures.

Asenapine (Saphris)

Indications. Asenapine is approved for the acute treatment of adults with schizophrenia and acute treatment of manic or mixed episodes associated with bipolar I disorder with or without psychotic features in adults.

Pharmacology. Asenapine has an affinity for several receptors, including serotonin (5-HT_{2A} and 5-HT_{2C}), noradrenergic (α_2, and α_1), dopaminergic (D_3 and D_4 receptors is higher than its affinity for D_2 receptors), and histamine (H_1). It has a negligible affinity for muscarinic-1 cholinergic receptors and hence less incidence of dry mouth, blurred vision, constipation, and urinary retention. The bioavailability is 35 percent via the sublingual (preferred) route, and it achieves peak plasma concentration in 1 hour. Asenapine is metabolized through glucuronidation and oxidative metabolism by CYP1A2, so coadministration with fluvoxamine and other CYP1A2 inhibitors should be done cautiously.

Dosage. Asenapine is available as 5- and 10-mg sublingual tablets and should be placed under the tongue. This method is because the bioavailability of asenapine is less than 2 percent when swallowed, but is 35 percent when

absorbed sublingually. The agent dissolves in saliva within seconds and is absorbed through the oral mucosa. Sublingual administration avoids first-pass hepatic metabolism. Patients should be advised to avoid drinking or eating for 10 minutes after taking asenapine because this may lower the blood levels. The recommended starting and target dose for schizophrenia is 5 mg twice a day. In bipolar disorder, the patient may be started on 10 mg twice a day, and if necessary, the dosage may be lowered to 5 mg twice a day, depending on the tolerability issues. In acute schizophrenia treatment, there is no evidence of added benefit with a 10 mg twice-daily dose, but there is an apparent increase in specific adverse reactions. In both bipolar I disorder and schizophrenia, the maximum dose should not exceed 10 mg two times a day. The safety of doses above 10 mg twice a day has not been evaluated in clinical studies.

Side Effects. The most common side effects observed in schizophrenic and bipolar disorders are somnolence, dizziness, EPS other than akathisia, and increased weight. In clinical trials, the mean weight gain after 52 weeks is 0.9 kg, and there were no clinically relevant differences in lipid profile and blood glucose after 52 weeks. In clinical trials, asenapine was found to increase the QTc interval in a range of 2 to 5 milliseconds compared to placebo. No patients treated with asenapine experienced QTc increases 60 milliseconds or greater from baseline measurements, nor did any experience a QTc of 500 milliseconds or more. Nevertheless, asenapine should be avoided in combination with other drugs known to prolong QTc interval in patients with congenital prolongation of QT interval or a history of cardiac arrhythmias, and in circumstances that may increase the occurrence of torsades de pointes. Asenapine can elevate prolactin levels, and the elevation can persist during chronic administration. Galactorrhea, amenorrhea, gynecomastia, and impotence may occur.

Clozapine (Clozaril)

Indications. In addition to being the most effective drug treatment for patients who have failed to respond to standard therapies, clozapine has been shown to benefit patients with severe tardive dyskinesia. Clozapine suppresses these dyskinesias, but the abnormal movements return when

clozapine is discontinued. This suppression is true even though clozapine, on rare occasions, may cause tardive dyskinesia. Other clinical situations in which clozapine may be used include the treatment of psychotic patients intolerant of EPS caused by other agents, treatment-resistant mania, severe psychotic depression, idiopathic Parkinson disease, Huntington disease, and suicidal patients with schizophrenia or schizoaffective disorder. Other treatment-resistant disorders that have demonstrated response to clozapine include pervasive developmental disorder, autism of childhood, and OCD (either alone or in combination with an SSRI). Used by itself, clozapine may very rarely induce obsessive-compulsive symptoms.

Pharmacology. Clozapine is a dibenzothiazepine. It is rapidly absorbed, with peak plasma levels reached in about 2 hours. Steady state is achieved in less than 1 week if twice-daily dosing is used. The elimination half-life is about 12 hours. Clozapine has two significant metabolites, one of which, *N*-dimethyl clozapine, may have some pharmacologic activities. Clozapine is an antagonist of 5-HT_{2A}, D_1, D_3, D_4, and α (especially $α_1$) receptors. It has relatively low potency as a D_2 receptor antagonist. Data from PET scanning show that whereas 10 mg of haloperidol produces 80 percent occupancy of striatal D_2 receptors, clinically significant dosages of clozapine occupy only 40 to 50 percent of striatal D_2 receptors. This difference in D_2 receptor occupancy is probably why clozapine does not cause EPS. It has also been postulated that clozapine and other SDAs bind more loosely to the D_2 receptor, and because of this "fast dissociation," more normal dopamine neurotransmission is possible.

Dosages. Clozapine is available in 25- and 100-mg tablets. The initial dosage is usually 25 mg one or two times daily, although a conservative initial dosage is 12.5 mg twice daily. The dosage can then be increased gradually (25 mg a day every 2 or 3 days) to 300 mg a day in divided doses, usually two or three times a day. Dosages up to 900 mg a day can be used. Testing for blood concentrations of clozapine may be helpful in patients who fail to respond. Studies have found that plasma concentrations greater than 350 µg/mL are associated with a better likelihood of response.

Drug Interactions. Clozapine should not be used with any other drug that is associated with the development of agranulocytosis or bone marrow suppression. Such drugs include carbamazepine, phenytoin, propylthiouracil, sulfonamides, and captopril (Capoten). Lithium combined with clozapine may increase the risk of seizures, confusion, and movement disorders. Lithium should not be used in combination with clozapine by persons who have experienced an episode of neuroleptic malignant syndrome. Clomipramine (Anafranil) can increase the risk of seizure by lowering the seizure threshold and by increasing clozapine plasma concentrations. Risperidone, fluoxetine, paroxetine, and fluvoxamine increase serum concentrations of clozapine. The addition of paroxetine may precipitate clozapine-associated neutropenia.

Side Effects. The most common drug-related adverse effects are sedation, dizziness, syncope, tachycardia, hypotension, electrocardiography (ECG) changes, nausea, and vomiting. Other common adverse effects include fatigue, weight gain, various GI symptoms (most commonly constipation), anticholinergic effects, and subjective muscle weakness. Sialorrhea, or hypersalivation, is a side effect that begins early in treatment and is most evident at night. Patients report that their pillows are drenched with saliva. This side effect is most likely the result of impairment of swallowing. Although there are reports that clonidine or amitriptyline may help reduce hypersalivation, the most practical solution is to put a towel over the pillow.

The risk of seizures is about 4 percent in patients taking dosages greater than 600 mg a day. Leukopenia, granulocytopenia, agranulocytosis, and fever occur in about 1 percent of patients. During the first year of treatment, there is a 0.73 percent risk of clozapine-
induced agranulocytosis. The risk during the second year is 0.07 percent. For neutropenia, the risk is 2.32 percent and 0.69 percent, respectively, during the first and second years of treatment. The only contraindications to the use of clozapine are a WBC count below 3,500 cells/mm^3; a previous bone marrow disorder; a history of agranulocytosis during clozapine treatment; or the use of another drug that is known to suppress the bone marrow, such as carbamazepine (Tegretol).

During the first 6 months of treatment, weekly WBC counts are indicated to monitor the patient for the development of agranulocytosis. If the WBC

count remains normal, the frequency of testing can be decreased to every 2 weeks. Although monitoring is expensive, an early indication of agranulocytosis can prevent a fatal outcome. Clozapine should be discontinued if the WBC count is below 3,000 cells/mm^3 or the granulocyte count is below 1,500/mm^3. Also, a hematologic consultation should be obtained, and obtaining a bone marrow sample should be considered. Persons with agranulocytosis should not be reexposed to the drug. Clozapine cannot be dispensed without proof of monitoring.

Patients exhibiting symptoms of chest pain, shortness of breath, fever, or tachypnea should be immediately evaluated for myocarditis or cardiomyopathy, an infrequent but serious adverse effect ending in death. Serial CPK-MB (creatine phosphokinase with myocardial band fractions), troponin levels, and ECG studies are recommended, with immediate discontinuation of clozapine.

Iloperidone (Fanapt)

Indications. Iloperidone (Fanapt) is indicated for the acute treatment of schizophrenia in adults. The safety and efficacy of iloperidone in children and adolescents has not been established.

Pharmacology. Iloperidone is not a derivative of another antipsychotic agent. It has complex multiple antagonist effects on several neurotransmitter systems. Iloperidone has a strong affinity for dopamine D_3 receptors, followed by decreasing affinities of α_{2c}-noradrenergic, 5-HT$_{1a}$, D_{2a}, and 5-HT$_6$ receptors. Iloperidone has a low affinity for histaminergic receptors. As with other antipsychotics, the clinical significance of this receptor binding affinity is unknown.

Iloperidone has a peak concentration of 2 to 4 hours and a half-life that is dependent on hepatic isoenzyme metabolism. It is metabolized primarily through CYP2D6 and CYP3A4, and the dosage should be reduced by half when administered concomitantly with potent inhibitors of these two isoenzymes. The half-life is 18 to 26 hours in CYP2D6 extensive metabolizers and is 31 to 37 hours in CYP2D6 poor metabolizers. Of note, approximately 7 to 10 percent of whites and 3 to 8 percent of African Americans cannot metabolize CYP2D6 substrates; hence, dosing should be

determined with this caveat in mind. Iloperidone should be used with caution in persons with severe hepatic impairment.

Side Effects. Iloperidone prolongs the QT interval and may be associated with arrhythmia and sudden death. Iloperidone prolongs the QTc interval by 9 milliseconds at dosages of 12 mg twice daily. Concurrent use with other agents that prolong the QTc interval may result in additive effects on the QTc interval. The concurrent use of iloperidone with agents that prolong the QTc interval may result in potentially life-threatening cardiac arrhythmias, including torsades de pointes. Concurrent administration of other drugs that are known to prolong the QTc interval should be avoided. Cardiovascular disease, hypokalemia, hypomagnesemia, bradycardia, congenital prolongation of the QT interval, and concurrent use of inhibitors of CYP3A4 or CYP2D6, which metabolize iloperidone, may increase the risk of QT prolongation.

The most common adverse effects reported are dizziness, dry mouth, fatigue, sedation, tachycardia, and orthostatic hypotension (depending on dosing and titration). Despite being a robust D_2 antagonist, the rates of EPS and akathisia are similar to those of placebo. The mean weight gain in short- and long-term trials is 2.1 kg. Due to its relatively limited use, there is no accurate understanding of iloperidone's effects on weight and lipids. Some patients exhibit elevated prolactin levels. Three cases of priapism have been reported in the premarketing phase.

Dosing. Iloperidone must be titrated slowly to avoid orthostatic hypotension. It is available in a titration pack, and the effective dose (12 mg) should be reached in approximately 4 days based on a twice-a-day dosing schedule. It is usually started on day 1 at 1 mg twice a day and increased daily on a twice-a-day schedule to reach 12 mg by day 4. The maximum recommended dose is 12 mg twice a day (24 mg a day), and it can be administered without regard to food.

Lurasidone HCL (Latuda)

Indications. Lurasidone hydrochloride is an oral, once-daily atypical antipsychotic indicated for the treatment of patients with schizophrenia. To

date, there has not been extensive clinical experience with lurasidone.

Side Effects. The most commonly observed adverse reactions associated with the use of lurasidone are similar to those seen with other new-generation antipsychotics. These include, but are not limited to, somnolence, akathisia, nausea, parkinsonism, and agitation. Based on clinical trial data, lurasidone appears to cause less weight gain and metabolic changes than the two other most recently approved SDAs, asenapine and iloperidone. More extensive clinical experience with the drug is required to determine whether this is, in fact, the case.

Drug Interactions. When coadministration of lurasidone with a moderate CYP3A4 inhibitor such as diltiazem is considered, the dose should not exceed 40 mg/day. Lurasidone should not be used in combination with a potent CYP3A4 inhibitor (e.g., ketoconazole). Lurasidone also should not be used in combination with a potent CYP3A4 inducer (e.g., rifampin).

Dosages. Lurasidone is available as 20-, 40-, 80-, and 120-mg tablets. Initial dose titration is not required. The recommended starting dose is 40 mg once daily, and the medication should be taken with food. It is effective in a dose range of 40 to 120 mg/day. Although there is no proven added benefit with the 120 mg/day dose, there may be a dose-related increase in adverse reactions. Still, some patients may benefit from the maximum recommended dose of 160 mg/day. Dose adjustment is recommended in patients with renal impairment. The dose in moderate to severe renal impairment should not exceed 80 mg/day. The dose in severe hepatic impairment patients should not exceed 40 mg/day.

Lumateperone (Caplyta)

Lumateperone was approved by the FDA for the treatment of schizophrenia in adults in December 2019 and became available in February 2020. It antagonizes several receptors, including 5-HT$_{2A}$ receptor, D$_1$, D$_2$, and D$_4$. Although effective for schizophrenia, several studies of its effectiveness in bipolar depression had disappointing results. It is available in several doses, although the highest FDA-approved dose is 42 mg. As this is a new drug, experience with it in post study clinical samples is very limited.

Clinical Guidelines for SDAs

All SDAs are appropriate for the management of an initial psychotic episode, but clozapine is reserved for persons who are refractory to all other antipsychotic drugs. If a person does not respond to the first SDA, other SDAs should be tried. The choice of drug should be based on the patient's clinical status and history of response to medication. Recent studies have challenged the notion that SDAs require 4 to 6 weeks to reach full effectiveness, and it may take up to 8 weeks for the full clinical effects of an SDA to become apparent. The newer meta-analyses suggest that the apparent benefits may be seen as early as 2 to 3 weeks, and early response or failure is an indicator of subsequent response or failure.

Nevertheless, it is acceptable practice to augment an SDA with a high-potency DRA or benzodiazepine in the first few weeks of use. Lorazepam (Ativan) 1 to 2 mg orally or IM can be used as needed for acute agitation. Once effective, dosages can be lowered as tolerated. Clinical improvement may take 6 months of treatment with SDAs in some, particularly treatment-refractory persons.

The use of all SDAs must be initiated at low dosages and gradually tapered upward to therapeutic dosages. The potential development of adverse effects necessitates the gradual increase in dosage. If a person stops taking an SDA for more than 36 hours, drug use should be resumed at the initial titration schedule. After the decision to terminate olanzapine or clozapine use, dosages should be tapered whenever possible to avoid cholinergic rebound symptoms such as diaphoresis, flushing, diarrhea, and hyperactivity.

After assuring themselves of the appropriateness of SDA treatment, the clinician should explain the risks and benefits of SDA treatment to the person and the family. In the case of clozapine, an informed consent procedure should be documented in the person's chart. The patient's history should include information about blood disorders, epilepsy, cardiovascular disease, hepatic and renal diseases, and drug abuse. The presence of a hepatic or renal disease necessitates using low starting dosages of the drug. The physical examination should include supine and standing BP measurements to screen for orthostatic hypotension. The laboratory examination should include an ECG and several complete blood counts (CBCs) with WBC counts, which can then be averaged; and liver and renal function tests. Periodic monitoring

of blood glucose, lipids, and body weight is recommended.

Although the transition from a DRA to an SDA may be made abruptly, it is wiser to taper off the DRA slowly while titrating up the SDA. Clozapine and olanzapine both have anticholinergic effects, and the transition from one to the other can usually be accomplished with little risk of cholinergic rebound. The transition from risperidone to olanzapine is best accomplished by tapering the risperidone off over 3 weeks while simultaneously beginning olanzapine at 10 mg a day. Risperidone, quetiapine, and ziprasidone lack anticholinergic effects, and the abrupt transition from a DRA, olanzapine, or clozapine to one of these agents may cause cholinergic rebound, which consists of excessive salivation, nausea, vomiting, and diarrhea. The risk of cholinergic rebound can be mitigated by initially augmenting risperidone, quetiapine, or ziprasidone with an anticholinergic drug, which is then tapered off slowly. Any initiation and termination of SDA use should be accomplished gradually.

It is wise to overlap the administration of the new drug with the old drug. Of interest, some people have a more robust clinical response while taking the two agents during the transition and then regressing on monotherapy with the newer drug. We know little about the safety of combination antipsychotic treatment.

Persons receiving regular injections of depot formulations of a DRA who are to switch to SDA use are given the first dose of the SDA on the day the next injection is due.

Persons who developed agranulocytosis while taking clozapine can safely switch to olanzapine use, although initiation of olanzapine use amid clozapine-induced agranulocytosis can prolong the time of recovery from the usual 3 to 4 days up to 11 to 12 days. It is prudent to wait for the resolution of agranulocytosis before initiating olanzapine use. Emergence or recurrence of agranulocytosis has not been reported with olanzapine, even in persons who developed it while taking clozapine.

SDA use by pregnant women has not been studied, but consideration should be given to the potential of risperidone to raise prolactin concentrations, sometimes up to three to four times the upper limit of the normal range. Because the drugs can be excreted in breast milk, they should not be taken by nursing mothers. The dosages for selected SDAs are given in Table 21-9.

DOPAMINE RECEPTOR ANTAGONISTS (FIRST-GENERATION ANTIPSYCHOTICS)

The DRAs represent the first group of effective agents for schizophrenia and other psychotic illnesses. The first of these drugs, the phenothiazine chlorpromazine (Thorazine), was introduced in the early 1950s. Other DRAs include all of the antipsychotics in the following groups: phenothiazines, butyrophenones, thioxanthenes, dibenzoxazepines, dihydroindoles, and diphenylbutylpiperidines. Because these agents are associated with extrapyramidal side effects (EPS) at clinically effective dosages, newer antipsychotic drugs—the SDAs—have gradually replaced the older agents in the United States. The SDAs are differentiated from earlier drugs by their lower liability to cause extrapyramidal side effects. These newer drugs have other liabilities, most notably a propensity to cause weight gain, lipid elevations, and diabetes. Therefore, a reason to still consider the use of the DRAs is their lower risk of causing significant metabolic abnormalities. Intermediate-potency DRAs, such as perphenazine (Trilafon), are as effective and well tolerated as the SDAs. Manufacturing of molindone (Moban), the DRA with the lowest risk of weight gain and metabolic side effects, was discontinued in the United States.

Table 21-9
Comparison of Usual Dosing*a* for Some Available Second-Generation Antipsychotics in Schizophrenia

Antipsychotic	Typical Starting Dosage	Maintenance Therapy Dose Range	Titration	Maximum Recommended Dosage
Aripiprazole (Abilify)	10–15 mg tablets once a day	10–30 mg/day	Dosage increases should not be made before 2 wk	30 mg/day
Asenapine (Saphris)	5 mg twice a day	10 mg twice a day	Titration not necessary	20 mg/day
Clozapine (Clozaril)	12.5-mg tablets once or twice a day	150–300 mg/day in divided doses or 200 mg as a single dose in the evening	The dosage should be increased to 25–50 mg on the second day. Further increases may be made in daily increments of 25–50 mg to a target dosage of 300–450 mg/day. Subsequent dosage increases should be made no more than once or twice weekly in increments of no more than 100 mg	900 mg/day
Iloperidone (Fanapt)	1 mg twice a day	12–24 mg a day in divided dose	Start at 1 mg twice a day then move to 2, 4, 6, 8 and 12 mg twice a day. Do this over the course of 7 days	24 mg/day
Lurasidone (Latuda)	40 mg/day	40–80 mg/day	Titration not necessary	120 mg/day
Olanzapine (Zyprexa)	5–10 mg/day tablets or orally disintegrating tablets	10–20 mg/day	Dosage increments of 5 mg once a day are recommended when required at intervals of not less than 1 wk	20 mg/day
Paliperidone (Invega)	3–9 mg extended-release tablets once a day	3–6 mg/day	Plasma concentration rises to a peak approximately 24 hr after dosing	12 mg/day
Quetiapine (Seroquel)	25-mg tablets twice a day	Lowest dose needed to maintain remission	Increase in increments of 25–50 mg two or three times a day on the second and the third day, as tolerated, to a target dosage of 500 mg daily by the fourth day (given in two or three doses/day). Further dosage adjustments, if required, should be of 25–50 mg twice a day and occur at intervals of not fewer than 2 days	800 mg/day
Risperidone (Risperdal)	1-mg tablet and oral solution once a day	2–6 mg once a day	Increase to 2 mg once a day on the second day and 4 mg once a day on the third day. In some patients, a slower titration may be appropriate. When dosage adjustments are necessary, further dosage increments of 1–2 mg/day at intervals of not less than 1 wk are recommended	1–6 mg/day
Risperidone IM long-acting (Consta)	25–50 mg IM injection every 2 wk	Start with oral risperidone for 3 wk	Starting dose: 25 mg every 2 wk	50 mg for 2 wk
Ziprasidone (Geodon)	20-mg capsules twice a day with food	20–80 mg twice a day	Dosage adjustments based on individual clinical status may be made at intervals of not fewer than 2 days	80 mg twice a day
Ziprasidone (IM)	For acute agitation: 10–20 mg, as required, up to a maximum of 40 mg/day	Not applicable	For acute agitation: Doses of 10 mg may be administered every 2 hr, and doses of 20 mg may be administered every 4 hr up to a maximum of 40 mg/day	For acute agitation: 40 mg/day, for not more than 3 consecutive days

Note: Information taken from U.S. Prescribing Information for individual agents.
*Dosage adjustments may be required in special populations.
IM, intramuscular.

Pharmacologic Actions

All of the DRAs are well absorbed after oral administration, with liquid preparations being absorbed more efficiently than tablets or capsules. Peak plasma concentrations are usually reached 1 to 4 hours after oral administration and 30 to 60 minutes after parenteral administration. Smoking, coffee, antacids, and food interfere with the absorption of these drugs. Steady-state levels are reached in approximately 3 to 5 days. The half-lives of these drugs are approximately 24 hours. All can be given in one daily oral

dose if tolerated after the patient is in a stable condition. Most DRAs are highly protein-bound. Parenteral formulation of the DRAs results in a more rapid and more reliable onset of action. Bioavailability is also up to 10-fold higher with parenteral administration. Most DRAs are metabolized by cytochrome P450 (CYP) CYP2D6 and 3A isozymes. However, there are differences among the specific agents.

Table 21-10
Factors Influencing the Pharmacokinetics of Antipsychotics

Age	Elderly patients may demonstrate reduced clearance rates.
Medical condition	Decreased hepatic blood flow can reduce clearance.
	Hepatic disease can decrease clearance.
Enzyme inducers	Carbamazepine, phenytoin, ethambutol, barbiturates.
Clearance inhibitors	Include SSRIs, TCAs, cimetidine, β-blockers, isoniazid, methylphenidate, erythromycin, triazolobenzodiazepines, ciprofloxacin, and ketoconazole.
Changes in binding protein	Hypoalbuminemia can occur with malnutrition or hepatic failure.

SSRI, selective serotonin reuptake inhibitor; TCA, tricyclic antidepressant.

Adapted from Ereshefsky L. Pharmacokinetics and drug interactions: update for new antipsychotics. *J Clin Psychiatry*. 1996;57(Suppl 11):12–25.

Long-acting depot parenteral formulations of haloperidol (Haldol Decanoate) and fluphenazine are available in the United States. These agents are usually administered once every 1 to 4 weeks, depending on the dose and the patient. It can take up to 6 months of treatment with depot formulations to reach steady-state plasma levels, indicating that oral therapy should be

continued during the first month or so of depot antipsychotic treatment.

Antipsychotic activity derives from the inhibition of dopaminergic neurotransmission. The DRAs are effective when approximately 72 percent of dopamine D_2 receptors in the brain are occupied. The DRAs also block noradrenergic, cholinergic, and histaminergic receptors, with different drugs having different effects on these receptor systems.

Some generalizations can be made about the DRAs based on their potency. Potency refers to the amount of drug that is required to achieve therapeutic effects. Low-potency drugs such as chlorpromazine and thioridazine (Mellaril), given in doses of several 100 mg/day, typically produce more weight gain and sedation than high-potency agents such as haloperidol and fluphenazine, usually given in doses of less than 10 mg/day. High-potency agents are also more likely to cause EPS. Some factors influencing the pharmacologic actions of DRAs are listed in Table 21-10.

Therapeutic Indications

Many types of psychiatric and neurologic disorders may benefit from treatment with DRAs. Some of these indications are shown in Table 21-11.

Schizophrenia and Schizoaffective Disorder. The DRAs are useful in both the short- and long-term management of schizophrenia and schizoaffective disorder. They both reduce acute symptoms and prevent future exacerbations. These agents produce their most dramatic effects on the positive symptoms of schizophrenia (e.g., hallucinations, delusions, and agitation). Negative symptoms (e.g., emotional withdrawal and ambivalence) are less likely to improve significantly, and they may appear to worsen because these drugs produce constriction of facial expression and akinesia, side effects that mimic negative symptoms.

Table 21-11
Indications for Dopamine Receptor Antagonists

Acute psychotic episodes in schizophrenia and schizoaffective disorder
Maintenance treatment in schizophrenia and schizoaffective

disorders
Mania
Depression with psychotic symptoms
Delusional disorder
Borderline personality disorder
Substance-induced psychotic disorder
Delirium and dementia
Mental disorders caused by a medical condition
Childhood schizophrenia
Autism spectrum disorder
Tourette disorder
Huntington disease

Schizophrenia and schizoaffective disorder are characterized by remission and relapse. DRAs decrease the risk of reemergence of psychosis in patients who have recovered while on medication. After the first episode of psychosis, patients should be maintained on medication for 1 to 2 years; after multiple episodes, for 2 to 5 years.

Mania. DRAs are useful for treating psychotic symptoms of acute mania. Because antimanic agents (e.g., lithium) generally have a slower onset of action than do antipsychotics in the treatment of acute symptoms, it is standard practice to initially combine either a DRA or an SDA with lithium (Eskalith), sodium valproate (Depakote), lamotrigine (Lamictal), or carbamazepine (Tegretol) and then to withdraw the antipsychotic gradually.

Depression with Psychotic Symptoms. Combination treatment with an antipsychotic and an antidepressant is one of the treatments of choice for MDD with psychotic features; the other is ECT.

Delusional Disorder. Patients with delusional disorder often respond favorably to treatment with these drugs. Some persons with borderline personality disorder who develop paranoid thinking may respond to antipsychotic drugs.

Severe Agitation and Violent Behavior. Severely agitated and violent patients, regardless of diagnosis, may be treated with DRAs. Symptoms such as extreme irritability, lack of impulse control, severe hostility, gross hyperactivity, and agitation respond to short-term treatment with these drugs. Children with mental disabilities, especially those with profound intellectual disabilities and autistic disorder, often have associated episodes of violence, aggression, and agitation that respond to treatment with antipsychotic drugs; however, the repeated administration of antipsychotics to control disruptive behavior in children is controversial.

Tourette Disorder. DRAs are used to treat Tourette's disorder, a neurobehavioral disorder marked by motor and vocal tics. Haloperidol and pimozide (Orap) are the drugs most frequently used, but other DRAs are also useful. Some clinicians prefer to use clonidine (Catapres) for this disorder because of its lower risk of neurologic side effects.

Borderline Personality Disorder. Patients with borderline personality disorder who experience transient psychotic symptoms, such as perceptual disturbances, suspiciousness, ideas of reference, and aggression, may need to be treated with a DRA. This disorder is also associated with mood instability, so patients should be evaluated for possible treatment with mood-stabilizing agents.

Dementia and Delirium. About two-thirds of agitated, elderly patients with various forms of dementia improve when given a DRA. Low doses of high-potency drugs (e.g., 0.5 to 1 mg a day of haloperidol) are recommended. DRAs are also used to treat psychotic symptoms and agitation associated with delirium. The cause of the delirium needs to be determined because toxic deliriums caused by anticholinergic agents can be exacerbated by low-potency DRAs, which often have significant antimuscarinic activity. Orthostasis, parkinsonism, and worsened cognition are the most problematic side effects in this elderly population.

Substance-Induced Psychotic Disorder. Intoxication with cocaine, amphetamines, alcohol, phencyclidine, or other drugs can cause psychotic symptoms. Because these symptoms tend to be time-limited, it is preferable

to avoid the use of a DRA unless the patient is severely agitated and aggressive. Usually, benzodiazepines can be used to calm the patient. Benzodiazepines should be used instead of DRAs in cases of phencyclidine intoxication. When a patient is experiencing hallucinations or delusions as a result of alcohol withdrawal, DRAs may increase the risk of seizure.

Childhood Schizophrenia. Children with schizophrenia benefit from treatment with antipsychotic medication, although considerably less research has been devoted to this population. Studies are underway to determine if intervention with medication at the very earliest signs of disturbance in children genetically at risk for schizophrenia can prevent the emergence of more florid symptoms. Careful consideration needs to be given to side effects, especially those involving cognition and alertness.

Table 21-12
Dopamine Receptor Antagonists: Potency and Adverse Effects

Drug Name	Chemical Classification	Therapeutically Equivalent Oral	Side Effects		
			Sedation	Autonomic[a]	Extrapyramidal Reactions[b]
Pimozide[c]	Diphenylbutyl-piperidine	1.5	+	+	+++
Fluphenazine	Phenothiazine: piperazine compound	2	+	+	+++
Haloperidol	Butyrophenone	2	+	+	+++
Thiothixene	Thioxanthene	4	+	+	+++
Trifluoperazine	Phenothiazine: piperazine compound	5	++	+	+++
Perphenazine	Phenothiazine: piperazine compound	8	++	+	++/+++
Molindone	Dihydroindolone	10	++	+	+
Loxapine	Dibenzoxazepine	10	++	+/++	++/+++
Prochlor-perazine[c]	Phenothiazine: piperazine compound	15	++	+	+++
Aceto-phenazine	Phenothiazine: piperazine compound	20	++	+	++/+++
Triflupromazine	Phenothiazine: aliphatic compound	25	+++	++/+++	++
Mesoridazine	Phenothiazine: piperidine compound	50	+++	++	+
Chlorpromazine	Phenothiazine: aliphatic compound	100	+++	+++	++
Chlorprothixene	Thioxanthene	100	+++	+++	+/++
Thioridazine	Phenothiazine: piperidine compound	100	+++	+++	+

[a]Anti–α-adrenergic and anticholinergic effects.
[b]Excluding tardive dyskinesia, which appears to be produced to the same degree and frequency by all agents with equieffective antipsychotic dosages.
[c]Pimozide is used principally in the treatment of Tourette disorder; prochlorperazine is used rarely, if ever, as an antipsychotic agent.
Adapted from American Medical Association. *AMA Drug Evaluations: Annual 1992.* Chicago: American Medical Association, 1992.

Other Psychiatric and Nonpsychiatric Indications. The DRAs reduce the chorea in the early stages of Huntington disease. Patients with this disease

may develop hallucinations, delusions, mania, or hypomania. These and other psychiatric symptoms respond to DRAs. High-potency DRAs should be used. However, clinicians should be aware that patients with a rigid form of this disorder may experience acute EPS. The use of DRAs to treat impulse control disorders should be reserved for patients in whom other interventions have failed. Patients with autism spectrum disorder may exhibit hyperactivity, screaming, and agitation with combativeness. Some of these symptoms respond to high-potency DRAs, but there is little research evidence supporting benefits in these patients.

The rare neurologic disorders ballismus and hemiballismus (which affect only one side of the body), characterized by propulsive movements of the limbs away from the body, also respond to treatment with antipsychotic agents. Other miscellaneous indications for the use of DRAs include the treatment of nausea, emesis, intractable hiccups, and pruritus. Endocrine disorders and temporal lobe epilepsy may be associated with psychosis that responds to antipsychotic treatment.

The most common side effects of DRAs are neurologic. As a rule, low-potency drugs cause the most nonneurologic adverse effects, and high-potency drugs cause the most neurologic adverse effects.

Precautions and Adverse Reactions

Table 21-12 summarizes the most common adverse events associated with the use of DRAs.

Neuroleptic Malignant Syndrome. A potentially fatal side effect of DRA treatment, neuroleptic malignant syndrome, can occur at any time during DRA treatment. Symptoms include extreme hyperthermia, severe muscular rigidity and dystonia, akinesia, mutism, confusion, agitation, and increased pulse rate and BP. Laboratory findings include increased WBC count and levels of creatinine phosphokinase, liver enzymes, plasma myoglobin, and myoglobinuria, occasionally associated with renal failure. The symptoms usually evolve over 24 to 72 hours, and the untreated syndrome lasts 10 to 14 days. The diagnosis is often missed in the early stages, and the withdrawal or agitation may mistakenly be considered to reflect increased psychosis. Men are affected more frequently than are

women, and young persons are affected more commonly than are elderly persons. The mortality rate can reach 20 to 30 percent, or even higher, when depot medications are involved. Rates are also increased when high doses of high-potency agents are used.

If the neuroleptic malignant syndrome is suspected, the DRA should be stopped immediately, and the following done: medical support to cool the person; monitoring of vital signs, electrolytes, fluid balance, and renal output; and symptomatic treatment of fever. Antiparkinsonian medications may reduce some of the muscle rigidity. Dantrolene (Dantrium), a skeletal muscle relaxant (0.8 to 2.5 mg/kg every 6 hours, up to a total dosage of 10 mg a day), may be useful in the treatment of this disorder. When the person can take oral medications, dantrolene can be given in doses of 100 to 200 mg a day. Bromocriptine (20 to 30 mg a day in four divided doses) or amantadine can be added to the regimen. Treatment should usually be continued for 5 to 10 days. When drug treatment is restarted, the clinician should consider switching to a low-potency drug or an SDA, although these agents— including clozapine—may also cause the neuroleptic malignant syndrome.

Seizure Threshold. DRAs may lower the seizure threshold. Chlorpromazine, thioridazine, and other low-potency drugs are thought to be more epileptogenic than are high-potency drugs. The risk of inducing a seizure by drug administration warrants consideration when the person already has a seizure disorder or brain lesion.

Sedation. The blockade of histamine H_1 receptors is the usual cause of sedation associated with DRAs. Chlorpromazine is the most sedating typical antipsychotic. The relative sedative properties of the drugs are summarized in Table 21-12. Giving the entire daily dose at bedtime usually eliminates any problems from sedation, and tolerance for this adverse effect often develops.

Central Anticholinergic Effects. The symptoms of central anticholinergic activity include severe agitation; disorientation to time, person, and place; hallucinations; seizures; high fever; and dilated pupils. Stupor and coma may ensue. The treatment of anticholinergic toxicity consists of discontinuing the causal agent or agents, close medical supervision, and physostigmine (Antilirium, Eserine), 2 mg by slow

intravenous (IV) infusion, repeated within 1 hour as necessary. Too much physostigmine is dangerous, and symptoms of physostigmine toxicity include hypersalivation and sweating. Atropine sulfate (0.5 mg) can reverse the effects of physostigmine toxicity.

Cardiac Effects. The DRAs decrease cardiac contractility, disrupt enzyme contractility in cardiac cells, increase circulating levels of catecholamines, and prolong atrial and ventricular conduction time and refractory periods. Low-potency DRAs, particularly the phenothiazines, are usually more cardiotoxic than are high-potency drugs. One exception is haloperidol, which has been linked to abnormal heart rhythm, ventricular arrhythmias, torsades de pointes, and sudden death when injected IV. Pimozide, sulpiride, and droperidol (a butyrophenone) also prolong the QTc interval and have been associated with torsades de pointes and sudden death. In one study, thioridazine was responsible for 28 (61 percent) of the 46 sudden antipsychotic deaths. In 15 of these cases, it was the only drug ingested. Chlorpromazine also causes prolongation of the QT and PR intervals, blunting of the T waves, and depression of the ST segment. These drugs are thus indicated only when other agents have been ineffective.

Sudden Death. Occasional reports of sudden cardiac death during treatment with DRAs may be the result of cardiac arrhythmias. Other causes may include seizure, asphyxiation, malignant hyperthermia, heatstroke, and neuroleptic malignant syndrome. However, there does seem to be an overall increased incidence of sudden death with antipsychotics.

Orthostatic (Postural) Hypotension. Orthostatic (postural) hypotension is most frequent with low-potency drugs, particularly chlorpromazine, thioridazine, and chlorprothixene. When using intramuscular (IM) low-potency DRAs, the clinician should measure the patient's BP (lying and standing) before and after the first dose and during the first few days of treatment.

Orthostatic hypotension is mediated by adrenergic blockade and occurs most frequently during the first few days of treatment. Tolerance often develops for this side effect, which is why the initial dosing of these drugs is lower than the usual therapeutic dose. Fainting or falls, although uncommon,

may lead to injury. Patients should be warned of this side effect and instructed to rise slowly after sitting and reclining. Patients should avoid all caffeine and alcohol; should drink at least 2 L of fluid a day; and if not under treatment for hypertension, should add liberal amounts of salt to their diet. Support hose may help some persons.

Hypotension can usually be managed by having patients lie down with their feet higher than their heads and pump their legs as if bicycling. Volume expansion or vasopressor agents, such as norepinephrine (Levophed), may be indicated in severe cases. Because hypotension is produced by α-adrenergic blockade, the drugs also block the α-adrenergic stimulating properties of epinephrine, leaving the β-adrenergic stimulating effects untouched. Therefore, the administration of epinephrine results in a paradoxical worsening of hypotension and is contraindicated in cases of antipsychotic-induced hypotension. Pure α-adrenergic pressor agents, such as metaraminol (Aramine) and norepinephrine, are the drugs of choice in the treatment of the disorder.

Hematologic Effects. Temporary leukopenia with a WBC count of about 3,500 is a common but not a serious problem. Agranulocytosis, a life-threatening hematologic problem, occurs in about 1 in 10,000 persons treated with DRAs. Thrombocytopenic or nonthrombocytopenic purpura, hemolytic anemias, and pancytopenia may rarely occur in persons treated with DRAs. Although routine CBCs are not indicated, if a person reports a sore throat and fever, a CBC should be done immediately to check for the possibility of a severe blood dyscrasia. If blood index values are low, the administration of DRAs should be stopped, and the patient should be transferred to a medical facility. The mortality rate for the complication may be as high as 30 percent.

Peripheral Anticholinergic Effects. Peripheral anticholinergic effects, such as dry mouth and nose, blurred vision, constipation, urinary retention, and mydriasis, are common. This is especially true with low-potency DRAs, for example, chlorpromazine, thioridazine, mesoridazine (Serentil). Some persons may also have nausea and vomiting.

Constipation should be treated with the usual laxative preparations, but severe constipation can progress to paralytic ileus. A decrease in the DRA dosage is warranted in such cases. Pilocarpine (Salagen) may be used to treat

paralytic ileus, although the relief is only transitory. Bethanechol (Urecholine) (20 to 40 mg a day) may be useful in some persons with urinary retention.

Weight gain is associated with increased mortality and morbidity and with medication noncompliance. Low-potency DRAs may cause significant weight gain but not as much as is seen with the SDAs olanzapine (Zyprexa) and clozapine (Clozaril). Molindone and perhaps loxapine (Loxitane) appear to be least likely to cause weight gain.

Endocrine Effects. Blockade of the dopamine receptors in the tuberoinfundibular tract results in the increased secretion of prolactin, which can result in breast enlargement, galactorrhea, amenorrhea, and inhibited orgasm in women and impotence in men. The SDAs, except risperidone (Risperdal), are not significantly associated with an increase in prolactin levels and may be the drugs of choice for persons experiencing disturbing side effects from increased prolactin release.

Sexual Adverse Effects. Both men and women taking DRAs can experience anorgasmia and decreased libido. Up to 50 percent of men who take antipsychotics report ejaculatory and erectile disturbances. Sildenafil (Viagra), vardenafil (Levitra), and tadalafil (Cialis) are often used to treat psychotropic-induced orgasmic dysfunction, but they have not been studied in combination with the DRAs. Thioridazine is mainly associated with decreased libido and retrograde ejaculation in men. Priapism and reports of painful orgasms have also been described, both possibly resulting from α_1-adrenergic antagonist activity.

Skin and Eye Effects. Allergic dermatitis and photosensitivity may occur, especially with low-potency agents. Urticarial, maculopapular, petechial, and edematous eruptions may occur early in treatment, generally in the first few weeks, and remit spontaneously. A photosensitivity reaction that resembles a severe sunburn also occurs in some persons taking chlorpromazine. Persons should be warned of this adverse effect, should spend no more than 30 to 60 minutes in the sun, and should use sunscreens. Long-term chlorpromazine use is associated with blue-gray discoloration of skin areas exposed to sunlight. The skin changes often begin with a tan or golden brown color and

progress to such colors as slate gray, metallic blue, and purple. These discolorations resolve when the patient is switched to another medication.

Irreversible retinal pigmentation is associated with the use of thioridazine at dosages above 1,000 mg a day. An early symptom of the side effect can sometimes be nocturnal confusion related to difficulty with night vision. The pigmentation can progress even after thioridazine administration is stopped, finally resulting in blindness. It is for this reason that the maximum recommended dosage of thioridazine is 800 mg/day.

Patients taking chlorpromazine may develop a relatively benign pigmentation of the eyes, characterized by whitish brown granular deposits concentrated in the anterior lens and posterior cornea and visible only by slit-lens examination. The deposits can progress to opaque white and yellow-brown granules, often stellate. Occasionally, the conjunctiva is discolored by a brown pigment. No retinal damage is seen, and vision is rarely impaired. This condition gradually resolves when chlorpromazine is discontinued.

Jaundice. Elevations of liver enzymes during treatment with a DRA tend to be transient and not clinically significant. When chlorpromazine first came into use, cases of obstructive or cholestatic jaundice were reported, usually in the first month of treatment and heralded by symptoms of upper abdominal pain, nausea, and vomiting. This adverse effect was followed by fever, rash, eosinophilia, bilirubin in the urine, and increases in levels of serum bilirubin, alkaline phosphatase, and hepatic transaminases. Reported cases are now sporadic, but if jaundice occurs, the medication should be discontinued.

Overdoses. Overdoses typically consist of exaggerated DRA side effects. Symptoms and signs include CNS depression, EPS, mydriasis, rigidity, restlessness, decreased deep tendon reflexes, tachycardia, and hypotension. The severe symptoms of overdose include delirium, coma, respiratory depression, and seizures. Haloperidol may be among the safest typical antipsychotics in overdose. After an overdose, electroencephalography (EEG) shows diffuse slowing and low voltage. An extreme overdose may lead to delirium and coma, with respiratory depression and hypotension. Life-threatening overdose usually involves the ingestion of other CNS depressants, such as alcohol or benzodiazepines.

Activated charcoal, if possible, and gastric lavage should be administered

if the overdose is recent. Emetics are not indicated because the antiemetic actions of the DRAs inhibit their efficacy. Seizures can be treated with IV diazepam or phenytoin. Hypotension can be treated with either norepinephrine or dopamine but not epinephrine.

Pregnancy and Lactation. There is a low correlation between the use of antipsychotics during pregnancy and congenital malformations. Nevertheless, antipsychotics should be avoided during pregnancy, particularly in the first trimester, unless the benefit outweighs the risk. High-potency drugs are preferable to low-potency drugs because low-potency drugs are associated with hypotension.

DRAs are secreted in the breast milk, although concentrations are low. Women taking these agents should be advised against breastfeeding.

Drug Interactions

Many pharmacokinetic and pharmacodynamic drug interactions are associated with these drugs (Table 21-13). CYP2D6 is the most common hepatic isozyme involved in DRA pharmacokinetic interactions. Other common drug interactions affect the absorption of the DRAs.

Antacids, activated charcoal, cholestyramine (Questran), kaolin, pectin, and cimetidine (Tagamet) taken within 2 hours of antipsychotic administration can reduce the absorption of these drugs. Anticholinergics may decrease the absorption of the DRAs. The additive anticholinergic activity of the DRAs, anticholinergics, and tricyclic drugs may result in anticholinergic toxicity. Digoxin (Lanoxin) and steroids, both of which decrease gastric motility, can increase DRA absorption.

Table 21-13
Antipsychotic Drug Interactions

Interacting Medication	Mechanism	Clinical Effect
Drug Interactions Assessed to Have Major Severity		
β-Adrenergic receptor	Synergistic pharmacologic effect; antipsychotic	Severe hypotension

antagonists	inhibits metabolism of propranolol; antipsychotic increases plasma concentrations	
Anticholinergics	Pharmacodynamic effects	Decreased antipsychotic effect
	Additive anticholinergic effect	Anticholinergic toxicity
Barbiturates	Phenobarbital induces antipsychotic metabolism	Decreased antipsychotic concentrations
Carbamazepine	Induces antipsychotic metabolism	Up to 50% reduction in antipsychotic concentrations
Charcoal	Reduces GI absorption of antipsychotic and adsorbs drug during enterohepatic circulation	May reduce antipsychotic effect or cause toxicity when used to treat overdose or for GI disturbances
Cigarette smoking	Induction of microsomal enzymes	Reduced plasma concentrations of antipsychotic agents
Epinephrine, norepinephrine	Antipsychotic antagonizes pressor effect	Hypotension
Ethanol	Additive CNS depression	Impaired psychomotor status

Fluvoxamine	Fluvoxamine inhibits metabolism of haloperidol and clozapine	Increased concentrations of haloperidol and clozapine
Guanethidine	Antipsychotic antagonizes guanethidine reuptake	Impaired antihypertensive effect
Lithium	Unknown	Rare reports of neurotoxicity
Meperidine	Additive CNS depression	Hypotension and sedation

Drug Interactions Assessed to Have Minor or Moderate Severity

Amphetamines, anorexiants	Decreased pharmacologic effect of amphetamine	Diminished weight loss effect; amphetamines may exacerbate psychosis
ACEIs	Additive hypotensive crisis	Hypotension, postural intolerance
Antacids containing aluminum	Insoluble complex formed in GI tract	Possible reduced antipsychotic effect
AD nonspecific	Decreased metabolism of AD through competitive inhibition	Increased AD concentration
Benzodiazepines	Increased pharmacologic effect of the benzodiazepine	Respiratory depression, stupor, hypotension

Bromocriptine	Antipsychotic antagonizes dopamine receptor stimulation	Increased prolactin
Caffeinated beverages	Form precipitate with antipsychotic solutions	Possible diminished antipsychotic effect
Cimetidine	Reduced antipsychotic absorption and clearance	Decreased antipsychotic effect
Clonidine	Antipsychotic potentiates α-adrenergic hypotensive effect	Hypotension or hypertension
Disulfiram	Impairs antipsychotic metabolism	Increased antipsychotic concentrations
Methyldopa	Unknown	BP elevations
Phenytoin	Induction of antipsychotic metabolism; decreased phenytoin metabolism	Decreased antipsychotic concentrations: increased phenytoin levels
SSRIs	Impair antipsychotic metabolism; pharmacodynamic interaction	Sudden onset of extrapyramidal symptoms
Valproic acid	Antipsychotic inhibits valproic acid metabolism	Increased valproic acid half-life and levels

ACEI, angiotensin-converting enzyme inhibitor; AD, antidepressant; BP, blood pressure; CNS, central nervous system; GI, gastrointestinal; SSRI, selective serotonin reuptake inhibitor.

From Ereshosky L, Overman GP, Karp JK. Current psychotropic dosing and monitoring guidelines. *Prim Psychiatry*. 1996;3:21, with permission.

Phenothiazines, especially thioridazine, may decrease the metabolism of and cause toxic concentrations of phenytoin. Barbiturates may increase the metabolism of DRAs.

Tricyclic drugs and SSRIs that inhibit CYP2D6—paroxetine (Paxil), fluoxetine (Prozac), and fluvoxamine (Luvox)—interact with DRAs, resulting in increased plasma concentrations of both drugs. The anticholinergic, sedative, and hypotensive effects of the drugs may also be cumulative.

Typical antipsychotics may inhibit the hypotensive effects of α-methyldopa (Aldomet). Conversely, typical antipsychotics may have an additive effect on some hypotensive drugs. Antipsychotic drugs have a variable effect on the hypotensive effects of clonidine. Propranolol (Inderal) coadministration increases the blood concentrations of both drugs.

The DRAs potentiate the CNS-depressant effects of the sedatives, antihistamines, opiates, opioids, and alcohol, particularly in persons with impaired respiratory status. When these agents are taken with alcohol, the risk for heatstroke may be increased.

Cigarette smoking may decrease the plasma levels of the typical antipsychotic drugs. Epinephrine has a paradoxical hypotensive effect in persons taking typical antipsychotics. These drugs may decrease the blood concentration of warfarin (Coumadin), resulting in decreased bleeding time. The phenothiazines, thioridazine, and pimozide should not be coadministered with other agents that prolong the QT interval. Thioridazine is contraindicated in patients taking drugs that inhibit the CYP2D6 isoenzyme or in patients with reduced levels of CYP2D6.

Laboratory Interferences

Chlorpromazine and perphenazine (Trilafon) may cause both false-positive and false-negative results in immunologic pregnancy tests and falsely elevated bilirubin (with reagent test strips) and urobilinogen (with Ehrlich reagent test) values. These drugs are associated with an abnormal shift in the results of the glucose tolerance test. However, that shift may reflect the effects of the drugs on the glucose-regulating system. Phenothiazines have been reported to interfere with the measurement of 17-ketosteroids and 17-hydroxycorticosteroids and produce false-positive results in tests for

phenylketonuria.

Dosage and Clinical Guidelines

Contraindications to the use of DRAs include the following: (1) a history of a severe allergic response; (2) the possible ingestion of a substance that will interact with the antipsychotic to induce CNS depression (e.g., alcohol, opioids, barbiturates, and benzodiazepines) or anticholinergic delirium (e.g., scopolamine and possibly phencyclidine [PCP]); (3) the presence of a severe cardiac abnormality; (4) a high risk for seizures; (5) the presence of narrow-angle glaucoma or prostatic hypertrophy if a drug with high anticholinergic activity is to be used; and (6) the presence or a history of tardive dyskinesia. Antipsychotics should be administered with caution in persons with hepatic disease because impaired hepatic metabolism may result in high plasma concentrations. The usual assessment should include a CBC with WBC indexes, liver function tests, and electrocardiography (ECG), especially in women older than 40 years of age and men older than 30 years of age. Elderly persons and children are more sensitive to side effects than are young adults, so the dosage of the drug should be adjusted accordingly.

Various patients may respond to widely different dosages of antipsychotics; therefore, there is no set dosage for any given antipsychotic drug. Because of side effects, it is a reasonable clinical practice to begin at a low dosage and increase as necessary. It is important to remember that the maximal effects of a particular dosage may not be evident for 4 to 6 weeks. Available preparations and dosages of the DRAs are given in Table 21-14.

Short-Term Treatment. The equivalent of 5 to 20 mg of haloperidol is a reasonable dose for an adult in an acute state. An older adult may benefit from as little as 1 mg of haloperidol. The administration of more than 25 mg of chlorpromazine in one injection may result in profound hypotension. IM administration results in peak plasma levels in about 30 minutes versus 90 minutes using the oral route. Doses of drugs for IM administration are about half those given by the oral route. In a short-term treatment setting, the person should be observed for 1 hour after the first dose of medication. After that time, most clinicians administer a second dose or a sedative agent (e.g., a benzodiazepine) to achieve effective behavioral control. Possible sedatives

include lorazepam (Ativan) (2 mg IM) and amobarbital (50 to 250 mg IM).

Rapid Neuroleptization. Rapid neuroleptization (also called psychotolysis) is the practice of administering hourly IM doses of antipsychotic medications until marked sedation is achieved. However, several research studies have shown that merely waiting several more hours after one dose yields the same clinical improvement as is seen with repeated doses. Nevertheless, clinicians must be careful to keep patients from becoming violent while they are psychotic. Clinicians can help prevent violent episodes by using adjuvant sedatives or by temporarily using physical restraints until the persons can control their behavior.

Early Treatment. A full 6 weeks may be necessary to evaluate the extent of the improvement in psychotic symptoms. However, agitation and excitement usually improve quickly with antipsychotic treatment. About 75 percent of persons with a short history of illness show significant improvement in their psychosis. Psychotic symptoms, both positive and negative, usually continue to improve 3 to 12 months after the initiation of treatment.

About 5 mg of haloperidol or 300 mg of chlorpromazine is a usual effective daily dose. In the past, much higher doses were used, but evidence suggests that it resulted in more side effects without additional benefits. A single daily dose is usually given at bedtime to help induce sleep and to reduce the incidence of adverse effects. However, bedtime dosing for elderly persons may increase their risk of falling if they get out of bed during the night. The sedative effects of typical antipsychotics last only a few hours, in contrast to the antipsychotic effects, which last for 1 to 3 days.

Intermittent Medications. It is a common clinical practice to order medications to be given intermittently as needed (PRN). Although this practice may be reasonable during the first few days that a person is hospitalized, the amount of time the person takes antipsychotic drugs, rather than an increase in dosage, is what produces therapeutic improvement. Clinicians on inpatient services may feel pressured by staff members to write PRN antipsychotic orders; such orders should include specific symptoms, how often the drugs should be given, and how many doses can be given each day. Clinicians may choose to use small doses for the PRN doses (e.g., 2 mg

of haloperidol) or use a benzodiazepine instead (e.g., 2 mg of lorazepam IM). If PRN doses of an antipsychotic are necessary after the first week of treatment, the clinician may want to consider increasing the standing daily dose of the drug.

Maintenance Treatment. The first 3 to 6 months after a psychotic episode are usually considered a period of stabilization. After that time, the dosage can be decreased by about 20 percent every 6 months until the minimum effective dosage is found. A person is usually maintained on antipsychotic medications for 1 to 2 years after the first psychotic episode. Antipsychotic treatment is often continued for 5 years after a second psychotic episode, and lifetime maintenance is considered after the third psychotic episode, although attempts to reduce the daily dosage can be made every 6 to 12 months.

Table 21-14
Dopamine Receptor Antagonists

Name						Rectal Suppositories (mg)	Adult Dose Range (mg/day)	
Generic or Chemical	Trade	Tablets (mg)	Capsules (mg)	Solution	Parenteral		Acute	Maintenance
Chlorpromazine	Thorazine	10, 25, 50, 100, 200	30, 75, 150, 200, 300	10 mg/5 mL, 30 mg/mL, 100 mg/mL	25 mg/mL	25, 100	100–1,600 PO, 25–400 IM	50–400 PO
Prochlorperazine	Compazine	5, 10, 25	10, 15, 30	5 mg/5 mL	5 mg/mL	2.5, 5, 25	15–200 PO, 40–80 IM	15–60 PO
Perphenazine	Trilafon	2, 4, 8, 16	—	16 mg/5 mL	5 mg/mL	—	12–64 PO, 15–30 IM	8–24 PO
Trifluoperazine	Stelazine	1, 2, 5, 10	—	10 mg/mL	2 mg/mL	—	4–40 PO, 4–10 IM	5–20 PO
Fluphenazine	Prolixin	1, 2.5, 5, 10	—	2.5 mg/5 mL, 5 mg/mL	2.5 mg/mL (IM only)	—	2.5–40.0 PO, 5–20 IM	1.0–15.0 PO, 12.5–50.0 IM (decanoate or enanthate, weekly or biweekly)
Fluphenazine decanoate	—	—	—	—	2.5 mg/mL	—	—	—
Fluphenazine enanthate	—	—	—	2.5 mg/mL	—	—	—	—
Thioridazine	Mellaril	10, 15, 25, 50, 100, 150, 200	—	25 mg/5 mL, 100 mg/5 mL, 30 mg/mL, 100 mg/mL	—	—	200–800 PO	100–300 PO
Mesoridazine	Serentil	10, 25, 50, 100	—	25 mg/mL	25 mg/mL	—	100–400 PO, 25–200 IM	30–150 PO
Haloperidol	Haldol	0.5, 1, 2, 5, 10, 20	—	2 mg/5 mL	5 mg/mL (IM only)	—	5–20 PO, 12.5–25 IM	1–10 PO
Haloperidol decanoate		—	—	—	50 mg/mL, 100 mg/mL (IM only)	—		25–200 IM (decanoate, monthly)
Chlorprothixene	Taractan	10, 25, 50, 100	—	100 mg/5 mL (suspension)	12.5 mg/mL	—	75–600 PO, 75–200 IM	50–400 PO
Thiothixene	Navane	—	1, 2, 5, 10, 20	5 mg/mL	5 mg/mL (IM only), 20 mg/mL (IM only)	—	60–100 PO, 8–30 IM	6–30 PO
Loxapine	Loxitane	—	5, 10, 25, 50	25 mg/5 mL	50 mg/mL	—	20–250 PO, 20–75 IM	20–100 PO
Molindone	Moban	5, 10, 25, 50, 100	—	20 mg/mL	—	—	50–225 PO	5–150 PO
Pimozide	Orap	2	—	—	—	—	0.5–20 PO	0.5–5.0 PO

IM, intramuscular; PO, oral.

Antipsychotic drugs are effective in controlling psychotic symptoms, but persons may report that they prefer being off the drugs because they feel better without them. The clinician must discuss maintenance medication with

patients and take into account their wishes, the severity of their illnesses, and the quality of their support systems. The clinician needs to know enough about the patient's life to try to predict upcoming stressors that might require increasing the dosage or closely monitoring compliance.

Long-Acting Depot Medications. Long-acting depot preparations may be needed to overcome problems with compliance. IM preparations are typically given once every 1 to 4 weeks.

Two depot preparations, a decanoate and an enanthate of fluphenazine, and a decanoate preparation of haloperidol, are available in the United States. The preparations are injected IM into an area of extensive muscle tissue, from which they are absorbed slowly into the blood. Decanoate preparations can be given less frequently than enanthate preparations because they are absorbed more slowly. Although stabilizing a person on the oral preparation of the specific drugs is not necessary before initiating the depot form, it is good practice to give at least one oral dose of the drug to assess the possibility of an adverse effect, such as severe EPS or an allergic reaction.

It is reasonable to begin with either 12.5 mg (0.5 mL) of fluphenazine preparation or 25 mg (0.5 mL) of haloperidol decanoate. If symptoms emerge in the next 2 to 4 weeks, the person can be treated temporarily with additional oral medications or with additional small depot injections. After 3 to 4 weeks, the depot injection can be increased to a single dose equal to the total of the doses given during the initial period.

A good reason to initiate depot treatment with low doses is that the absorption of the preparations may be faster than usual at the onset of treatment, resulting in frightening episodes of dystonia that eventually discourage compliance with the medication. Some clinicians keep patients drug free for 3 to 7 days before initiating depot treatment and give small doses of the depot preparations (3.125 mg of fluphenazine or 6.25 mg of haloperidol) every few days to avoid those initial problems.

Plasma Concentrations

Genetic differences among persons and pharmacokinetic interactions with other drugs influence the metabolism of the antipsychotics. If a person has not improved after 4 to 6 weeks of treatment, the plasma concentration of the

drug should be determined if feasible. After a patient has been on a particular dosage for at least five times the half-life of the drug and thus approaches steady-state concentrations, blood levels may be helpful. It is standard practice to obtain plasma samples at trough levels—just before the daily dose is given, usually at least 12 hours after the previous dose, and most commonly 20 to 24 hours after the previous dose. Most antipsychotics have no well-defined dose–response curve. The best-studied drug is haloperidol, which may have a therapeutic window ranging from 2 to 15 ng/mL. Other therapeutic ranges that have been reasonably well documented are 30 to 100 ng/mL for chlorpromazine and 0.8 to 2.4 ng/mL for perphenazine.

Treatment-Resistant Persons. Unfortunately, 10 to 35 percent of persons with schizophrenia do not obtain significant benefit from the antipsychotic drugs. Treatment resistance is a failure on at least two adequate trials of antipsychotics from two pharmacologic classes. It is useful to determine plasma concentrations for such persons because it is possible that they are slow or rapid metabolizers or are not taking their medication. Clozapine has been conclusively shown to be effective when given to patients who have failed multiple trials of DRAs.

Adjunctive Medications. It is common practice to use DRAs in conjunction with other psychotropic agents, either to treat side effects or to improve symptoms further. Most commonly, this involves the use of lithium or other mood-stabilizing agents, SSRIs, or benzodiazepines. It was once held that antidepressant drugs exacerbated psychosis in patients with schizophrenia. In all likelihood, this observation involved patients with bipolar disorder who were misdiagnosed as having schizophrenia. Abundant evidence suggests that antidepressants improve symptoms of depression in patients with schizophrenia. In some cases, amphetamines can be added to DRAs if patients remain withdrawn and apathetic.

Choice of Drug

Given their proven efficacy in managing acute psychotic symptoms and the fact that prophylactic administration of antiparkinsonian medication prevents or minimizes acute motor abnormalities, DRAs are still valuable, especially for short-term therapy. There is a considerable cost advantage to a DRA

antiparkinsonian regimen compared with monotherapy with a newer antipsychotic agent. Concern about the development of DRA-induced tardive dyskinesia is the primary deterrent to long-term use of these drugs, yet it is not clear that SDAs are entirely free of this complication. Thus, DRAs still occupy an important role in psychiatric treatment. DRAs are not predictably interchangeable. For reasons that cannot be explained, some patients do better on one drug than another. The choice of a particular DRA should be based on the known adverse effect profile of the drugs. Other than a significant advantage in terms of medication cost, the choice currently would be an SDA. If a DRA is thought to be preferable, a high-potency antipsychotic is favored, even though it may be associated with more neurologic adverse effects, mainly because there is a higher incidence of other adverse effects (e.g., cardiac, hypotensive, epileptogenic, sexual, and allergic) with the low-potency drugs. If sedation is the desired goal, either a low-potency antipsychotic can be given in divided doses, or a benzodiazepine can be coadministered.

An unpleasant or dysphoric reaction (a subjective sense of restlessness, oversedation, and acute dystonia) to the first dose of an antipsychotic predicts future inadequate response and noncompliance. Prophylactic use of antiparkinsonian medications may prevent this reaction. In general, clinicians should be vigilant about serious side effects and adverse events (described above) regardless of which drug is used.

▲ 21.2 Antidepressants

SELECTIVE SEROTONIN REUPTAKE INHIBITORS

Fluoxetine (Prozac), the first SSRI marketed in the United States, rapidly captured the favor of both clinicians and the general public as reports emerged of dramatic patient responses to treatment of depression. Patients no longer experienced such side effects as dry mouth, constipation, sedation, orthostatic hypotension, and tachycardia, typical side effects associated with the earlier antidepressant drugs—the TCAs and MAOIs. It was also significantly safer when taken in overdose than any previously available antidepressant. A significant effect of fluoxetine's popularity was that it helped ameliorate the long-standing stigma of depression and its treatment.

Table 21-15

Currently Approved Indications of the Selective Serotonin Reuptake Inhibitors in the United States for Adult and Pediatric Populations

	Citalopram (Celexa)	Escitalopram (Lexapro)	Fluoxetine (Prozac)	Fluvoxamine (Luvox)	Paroxetine (Paxil)	Sertraline (Zoloft)	Vilazodone (Viibryd)
Major depressive disorder	Adult	Adult	Adult[a] and pediatric	—	Adult[b]	Adult	Adult

Social anxiety disorder	—	—	—	—	Adult[b]	Adult	—
Bulimia nervosa	—	—	Adult	—	—	—	—
Premenstrual dysphoric disorder	—	—	Adult[c]	—	Adult[d]	Adult	—

OCD, obsessive-compulsive disorder; PTSD, posttraumatic stress disorder.
[a] Weekly fluoxetine is approved for continuation and maintenance therapy in adults.
[b] Paroxetine and paroxetine controlled-release.
[c] Marketed as Sarafem.
[d] Paroxetine-controlled release is approved for premenstrual dysphoric disorder.

Other SSRIs followed fluoxetine. These include sertraline (Zoloft), paroxetine (Paxil), fluvoxamine (Luvox), citalopram (Celexa), escitalopram (Lexapro), and vilazodone (Viibryd). These drugs are all equally effective in

treating depression. However, some are approved by the U.S. FDA for multiple indications, such as major depression, OCD, PTSD, PMDD, panic disorder, and social phobia (social anxiety disorder) (Table 21-15). Note that fluvoxamine is not FDA approved as an antidepressant, a fact that is due to a marketing decision. It is considered an antidepressant in other countries.

Although all SSRIs are equally effective, there are meaningful differences in pharmacodynamics, pharmacokinetics, and side effects, differences that might affect clinical responses among individual patients. This would explain why some patients have better clinical responses to a particular SSRI than another. The SSRIs have proven more problematic in terms of some side effects than the original clinical trials suggested. Quality-of-life–associated adverse effects such as nausea, sexual dysfunction, and weight gain sometimes mitigate the therapeutic benefits of the SSRIs. There can also be distressing withdrawal symptoms when SSRIs are stopped abruptly. This withdrawal is especially true with paroxetine but also occurs when other SSRIs with short half-lives are stopped.

Pharmacologic Actions

Pharmacokinetics. A significant difference among the SSRIs is their broad range of serum half-lives. Fluoxetine has the most prolonged half-life: 4 to 6 days; its active metabolite has a half-life of 7 to 9 days. The half-life of sertraline is 26 hours, and its less active metabolite has a half-life of 3 to 5 days. The half-lives of the other three, which do not have metabolites with significant pharmacologic activity, are 35 hours for citalopram, 27 to 32 hours for escitalopram, 21 hours for paroxetine, and 15 hours for fluvoxamine. As a rule, the SSRIs are well absorbed after oral administration and have their peak effects in the range of 3 to 8 hours. Absorption of sertraline may be slightly enhanced by food.

There are also differences in plasma protein–binding percentages among the SSRIs, with sertraline, fluoxetine, and paroxetine being the most highly bound and escitalopram being the least bound.

All SSRIs are metabolized in the liver by the CYP450 enzymes. Because the SSRIs have such a broad therapeutic index, other drugs rarely produce problematic increases in SSRI concentrations. The most critical drug–drug interactions involving the SSRIs occur as a result of the SSRIs inhibiting the

metabolism of the coadministered medication. Each of the SSRIs possesses a potential for slowing or blocking the metabolism of many drugs (Table 21-16). Fluvoxamine is the most problematic of the drugs in this respect. It has a marked effect on several of the CYP enzymes. Examples of clinically significant interactions include fluvoxamine and theophylline (Slo-Bid, Theo-Dur) through CYP1A2 interaction, fluvoxamine and clozapine (Clozaril) through CYP1A2 inhibition; and fluvoxamine with alprazolam (Xanax) or clonazepam (Klonopin) through CYP3A4 inhibition. Fluoxetine and paroxetine also possess significant effects on the CYP2D6 isozyme, which may interfere with the efficacy of opiate analogs, such as codeine and hydrocodone, by blocking the conversion of these agents to their active form. Thus, coadministration of fluoxetine and paroxetine with an opiate interferes with its analgesic effects. Sertraline, citalopram, and escitalopram are least likely to complicate treatment because of interactions.

The pharmacokinetics of vilazodone (5 to 80 mg) is dose-proportional. Steady-state plasma levels are achieved in about 3 days. The elimination of vilazodone is primarily by hepatic metabolism with a terminal half-life of approximately 25 hours.

Pharmacodynamics. The SSRIs are believed to exert their therapeutic effects through serotonin reuptake inhibition. They derive their name because they have little effect on the reuptake of norepinephrine or dopamine. Often, adequate clinical activity and saturation of the 5-HT transporters are achieved at starting dosages. As a rule, higher dosages do not increase antidepressant efficacy but may increase the risk of adverse effects.

Table 21-16
CYP450 Inhibitory Potential of Commonly Prescribed Antidepressants

Relative Rank	CYP1A2	CYP2C	CYP2D6	CYP3A
Higher	Fluvoxamine (Luvox)	Fluoxetine Fluvoxamine	Bupropion Fluoxetine Paroxetine	Fluvoxamine Nefazodone Tricyclics
Moderate	Tertiary amine tricyclics Fluoxetine (Prozac)	Sertraline	Secondary amine tricyclics Citalopram (Celexa) Escitalopram (Lexapro) Sertraline	Fluoxetine Sertraline
Low or minimal	Bupropion (Wellbutrin) Mirtazapine (Remeron) Nefazodone (Serzone) Paroxetine (Paxil) Sertraline (Zoloft) Venlafaxine (Effexor)	Paroxetine Venlafaxine	Fluvoxamine Mirtazapine Nefazodone Venlafaxine	Citalopram Escitalopram Mirtazapine Paroxetine Venlafaxine

CYP, cytochrome P450.

Citalopram and escitalopram are the most selective inhibitors of serotonin reuptake, with very little inhibition of norepinephrine or dopamine reuptake and very low affinities for histamine H_1, GABA, or benzodiazepine receptors. The other SSRIs have a similar profile except that fluoxetine weakly inhibits norepinephrine reuptake and binds to 5-HT_{2C} receptors, sertraline weakly inhibits norepinephrine and dopamine reuptake, and paroxetine has significant anticholinergic activity at higher dosages and binds to nitric oxide synthase. The SSRI vilazodone has 5-HT_{1A} receptor agonist properties. The clinical implications of the 5-HT_{1A} receptor agonist effects are not yet evident.

A pharmacodynamic interaction appears to underlie the antidepressant effects of combined fluoxetine–olanzapine. When taken together, these drugs increase brain concentrations of norepinephrine. Concomitant use of SSRIs and drugs in the triptan class (sumatriptan [Imitrex], naratriptan [Amerge], rizatriptan [Maxalt], and zolmitriptan [Zomig]) may result in a severe pharmacodynamic interaction—the development of serotonin syndrome (see "Precautions and Adverse Reactions"). However, many people use triptans while taking low doses of an SSRI for headache prophylaxis without adverse reaction. A similar reaction may occur when SSRIs are combined with tramadol (Ultram).

Therapeutic Indications

Depression. In the United States, all SSRIs other than fluvoxamine have been approved by the FDA for the treatment of depression. Several studies

have found that antidepressants with serotonin-norepinephrine activity—drugs such as the MAOIs, TCAs, venlafaxine (Effexor), and mirtazapine (Remeron)—may produce higher rates of remission than SSRIs in head-to-head studies. The continued role of SSRIs as first-line treatment thus reflects their simplicity of use, safety, and a broad spectrum of action.

Direct comparisons of individual SSRIs have not revealed any to be consistently superior to another. There nevertheless can be considerable diversity in response to the various SSRIs among individuals. For example, more than 50 percent of people who respond poorly to one SSRI will respond favorably to another. Thus, before shifting to non-SSRI antidepressants, it is most reasonable to try other agents in the SSRI class for persons who did not respond to the first SSRI.

Some clinicians have attempted to select a particular SSRI for a specific person based on the drug's unique adverse effect profile. For example, thinking that fluoxetine is an activating and stimulating SSRI, they may assume it is a better choice for an abulic person than paroxetine, which is presumed to be a sedating SSRI. These differences, however, usually vary from person to person. Analyses of clinical trial data show that SSRIs are more effective in patients with more severe symptoms of major depression than those with milder symptoms.

SUICIDE. The FDA has issued a black box warning for antidepressants and suicidal thoughts and behavior in children and young adults. This warning is based on a decade-old analysis of clinical trial data. More recent, comprehensive reanalysis of data has shown that suicidal thoughts and behavior decreased over time for adult and geriatric patients treated with antidepressants as compared with placebo. No differences were found for youths. In adults, reduction in suicide ideation and attempts occurred through a reduction in depressive symptoms. In all age groups, the severity of depression improved with medication and was significantly related to suicide ideation or behavior. It appears that SSRIs, as well as serotonin-norepinephrine reuptake inhibitors (SNRIs), have a protective effect against suicide that is mediated by decreases in depressive symptoms with treatment. For youths, no significant effects of treatment on suicidal thoughts and behavior were found, although depression responded to treatment. No evidence of increased suicide risk was observed in youths receiving active

medication. It is crucial to keep in mind that SSRIs, like all antidepressants, prevent potential suicides as a result of their primary action, the shortening and prevention of depressive episodes. In clinical practice, a few patients become anxious and agitated when started on an SSRI. The appearance of these symptoms could conceivably provoke or aggravate suicidal ideation. Thus, all depressed patients should be closely monitored during the period of maximum risk, the first few days and weeks they are taking SSRIs.

DEPRESSION DURING PREGNANCY AND POSTPARTUM. Rates of relapse of major depression during pregnancy among women who discontinue, attempt to discontinue, or modify their antidepressant regimens are very high. Rates range from 68 to 100 percent of patients. Thus, many women need to continue taking their medication during pregnancy and postpartum. The impact of maternal depression on infant development is unknown. There is no significantly increased risk for major congenital malformations after exposure to SSRIs during pregnancy (with the exception of paroxetine, discussed below). Thus, the risk of relapse into depression when a newly pregnant mother is taken off SSRIs is severalfold higher than the risk to the fetus of exposure to SSRIs.

There is some evidence suggesting increased rates of special care nursery admissions after delivery for children of mothers taking SSRIs. There is also a potential for a discontinuation syndrome with paroxetine. However, there is an absence of clinically significant neonatal complications associated with SSRI use.

Studies that have followed children into their early school years have failed to find any perinatal complications, congenital fetal anomalies, decreases in global intelligence quotient (IQ), language delays, or specific behavioral problems attributable to the use of fluoxetine during pregnancy.

Postpartum depression (with or without psychotic features) affects a small percentage of mothers. Some clinicians start administering SSRIs if the postpartum blues extend beyond a few weeks or if a woman becomes depressed during pregnancy. The head start afforded by starting SSRI administration during pregnancy if a woman is at risk for postpartum depression also protects the newborn, toward whom the woman may have harmful thoughts after parturition.

Babies whose mothers are taking an SSRI in the latter part of pregnancy

may be at a slight risk of developing pulmonary hypertension. Data about the risk of this side effect are inconclusive, but it is estimated to involve 1 to 2 babies for 1,000 births. Paroxetine should be avoided during pregnancy.

The FDA classified paroxetine as a pregnancy Category D medication in the former FDA classification system. In 2005, the FDA issued an alert that paroxetine increases the risk of congenital disabilities, particularly heart defects, when women take it during the first 3 months of pregnancy. Paroxetine should usually not be taken during pregnancy, but for some women who have already been taking paroxetine, the benefits of continuing paroxetine may be greater than the potential risk to the baby. Women taking paroxetine who are pregnant, think they may be pregnant, or plan to become pregnant should talk to their physicians about the potential risks of taking paroxetine during pregnancy.

The FDA alert was based on the findings of studies that showed that women who took paroxetine during the first 3 months of pregnancy were about one-and-a-half to two times as likely to have a baby with a heart defect as women who received other antidepressants or women in the general population. Most of the heart defects in these studies were not life-threatening and happened mainly in the inside walls of the heart muscle, where repairs can be made if needed (atrial and ventricular septal defects). Sometimes these septal defects resolve without treatment. In one of the studies, the risk of heart defects in babies whose mothers had taken paroxetine early in pregnancy was 2 percent, compared with a 1 percent risk in the whole population. In the other study, the risk of heart defects in babies whose mothers had taken paroxetine in the first 3 months of pregnancy was 1.5 percent, compared with 1 percent in babies whose mothers had taken other antidepressants in the first 3 months of pregnancy. This study also showed that women who took paroxetine in the first 3 months of pregnancy were about twice as likely to have a baby with any congenital disability as women who took other antidepressants.

Minimal amounts of SSRIs are found in breast milk, and no harmful effects have been found in breastfed babies. Concentrations of sertraline and escitalopram are exceptionally low in breast milk. However, in some cases, reported concentrations might be higher than average. No decision regarding the use of an SSRI is risk-free. It is thus essential to document that communication of potential risks to the patient has taken place.

DEPRESSION IN ELDERLY AND MEDICALLY ILL PERSONS. The SSRIs are safe and well tolerated when used to treat elderly and medically ill persons. As a class, they have little or no cardiotoxic, anticholinergic, antihistaminergic, or α-adrenergic adverse effects. Paroxetine does have some anticholinergic activity, which may lead to constipation and worsening of cognition. The SSRIs can produce subtle cognitive deficits, prolonged bleeding time, and hyponatremia, all of which may impact the health of this population. The SSRIs are effective in poststroke depression and dramatically reduce the symptom of crying.

DEPRESSION IN CHILDREN. The use of SSRI antidepressants in children and adolescents has been controversial. Few studies have shown clear-cut benefits from the use of these drugs, and studies show that there may be an increase in suicidal or aggressive impulses. However, some children and adolescents do exhibit dramatic responses to these drugs in terms of depression and anxiety. Fluoxetine has most consistently demonstrated effectiveness in reducing symptoms of depressive disorder in both children and adolescents. This fact may be a function of the quality of the clinical trials involved. Sertraline is effective in treating social anxiety disorder in this population, especially when combined with cognitive-behavioral therapy. Given the potential adverse effect of untreated depression and anxiety in a young population and the uncertainty about many aspects of how children and adolescents might react to medication, any use of SSRIs should be undertaken only within the context of comprehensive management of the patient.

Anxiety Disorders

OBSESSIVE-COMPULSIVE DISORDER. Fluvoxamine, paroxetine, sertraline, and fluoxetine are indicated for the treatment of OCD in persons older than the age of 18 years. Fluvoxamine, fluoxetine, and sertraline have also been approved for the treatment of children with OCD (ages 6 to 17 years). About 50 percent of persons with OCD begin to show symptoms in childhood or adolescence, and more than half of these respond favorably to medication. Beneficial responses can be dramatic. Long-term data support the model of

OCD as a genetically determined, lifelong condition that is best treated continuously with drugs and cognitive-behavioral therapy from the onset of symptoms in childhood throughout the lifespan.

SSRI dosages for OCD may need to be higher than those required to treat depression. Although some responses can be seen in the first few weeks of treatment, it may take several months for the maximum effects to become evident. Patients who fail to obtain adequate relief of their OCD symptoms with an SSRI will usually benefit from the addition of a small dose of risperidone (Risperdal). Apart from the extrapyramidal side effects of risperidone, patients should be monitored for increases in prolactin levels when this combination is used. Clinically, hyperprolactinemia may manifest as gynecomastia and galactorrhea (in both men and women) and loss of menses.

Several disorders are now considered to be within the OCD spectrum. This spectrum includes several conditions and symptoms characterized by nonsuicidal self-mutilation, such as trichotillomania, eyebrow picking, nose picking, nail-biting, compulsive picking of skin blemishes, and cutting. Patients with these behaviors benefit from treatment with SSRIs. Other spectrum disorders include compulsive gambling, compulsive shopping, hypochondriasis, and body dysmorphic disorder.

PANIC DISORDER. Paroxetine, fluoxetine, and sertraline are indicated for the treatment of panic disorder, with or without agoraphobia. These agents work less rapidly than do benzodiazepines but are far superior to them for the treatment of panic disorder with comorbid depression. Citalopram and fluvoxamine also may reduce spontaneous or induced panic attacks. Because fluoxetine can initially heighten anxiety symptoms, persons with panic disorder must begin taking small dosages (5 mg a day) and increase the dosage slowly. Low doses of benzodiazepines may be given to manage this side effect.

SOCIAL ANXIETY DISORDER. SSRIs are effective agents in the treatment of social phobia. They reduce both symptoms and disability. The response rate is comparable to that seen with the MAOI phenelzine (Nardil), the previous standard treatment. The SSRIs are safer to use than MAOIs or benzodiazepines.

POSTTRAUMATIC STRESS DISORDER. Pharmacotherapy for PTSD must target specific symptoms in four clusters: reexperiencing, avoidance, negative changes in mood and thinking, and arousal. For long-term treatment, SSRIs appear to have a broader spectrum of therapeutic effects on specific PTSD symptom clusters than do TCAs and MAOIs. Benzodiazepine augmentation is useful in the acute symptomatic state. The SSRIs are associated with marked improvement of both intrusive and avoidant symptoms.

GENERALIZED ANXIETY DISORDER. The SSRIs may be useful for the treatment of specific phobias, generalized anxiety disorder (GAD), and separation anxiety disorder. A thorough, individualized evaluation is the first approach, with particular attention to identifying conditions amenable to drug therapy. Also, cognitive-behavioral or other psychotherapies can be added for greater efficacy.

Bulimia Nervosa and Other Eating Disorders.

Fluoxetine is indicated for the treatment of bulimia, which is best done in the context of psychotherapy. Dosages of 60 mg a day are significantly more effective than 20 mg a day. In several well-controlled studies, fluoxetine in dosages of 60 mg a day was superior to placebo in reducing binge eating and induced vomiting. Some experts recommend an initial course of cognitive-behavioral therapy alone. If there is no response in 3 to 6 weeks, then fluoxetine administration is added. The appropriate duration of treatment with fluoxetine and psychotherapy has not been determined.

Fluvoxamine was not effective at a statistically significant level in one double-blind, placebo-controlled trial for inpatients with bulimia.

ANOREXIA NERVOSA. Fluoxetine has been used in inpatient treatment of anorexia nervosa to attempt to control comorbid mood disturbances and obsessive-compulsive symptoms. However, at least two careful studies, one of 7 months' and one of 24 months' duration, failed to find that fluoxetine affected the overall outcome and the maintenance of weight. Effective treatments for anorexia include cognitive-behavioral, interpersonal, psychodynamic, and family therapies in addition to a trial with SSRIs.

OBESITY. Fluoxetine, in combination with a behavioral program, is only

modestly beneficial for weight loss. A significant percentage of all persons who take SSRIs, including fluoxetine, lose weight initially but later may gain weight. However, all SSRIs may cause initial weight gain.

PREMENSTRUAL DYSPHORIC DISORDER. PMDD is characterized by debilitating mood and behavioral changes in the week preceding menstruation that interferes with normal functioning. Sertraline, paroxetine, fluoxetine, and fluvoxamine have been reported to reduce the symptoms of PMDD. Controlled trials of fluoxetine and sertraline administered either throughout the cycle or only during the luteal phase (the 2 weeks between ovulation and menstruation) showed both schedules to be equally effective.

An additional observation of unclear significance was that fluoxetine was associated with changing the duration of the menstrual period by more than 4 days, either lengthening or shortening it. The effects of SSRIs on menstrual cycle length are mostly unknown and may warrant careful monitoring in women of reproductive age.

Off-Label Uses

PREMATURE EJACULATION. The anorgasmic effects of SSRIs make them useful as a treatment for men with premature ejaculation. The SSRIs permit intercourse for a significantly more extended period and are reported to improve sexual satisfaction in couples in which the man has premature ejaculation. Fluoxetine and sertraline are useful for this purpose.

PARAPHILIAS. The SSRIs may reduce obsessive-compulsive behavior in people with paraphilias. The SSRIs diminish the average time per day spent in unconventional sexual fantasies, urges, and activities. Evidence suggests a more significant response to sexual obsessions than for paraphilic behavior.

AUTISM. Obsessive-compulsive behavior, poor social relatedness, and aggression are prominent autistic features that may respond to serotonergic agents such as SSRIs and clomipramine (Anafranil). Sertraline and fluvoxamine have been shown in controlled and open-label trials to mitigate aggressiveness, self-injurious behavior, repetitive behaviors, some degree of language delay, and (rarely) lack of social relatedness in adults with autistic

spectrum disorders. Fluoxetine has been reported to be useful for features of autism in children, adolescents, and adults.

Precautions and Adverse Reactions. SSRI side effects need to be considered in terms of their onset, duration, and severity. For example, nausea and jitteriness are early, generally mild, and time-limited side effects. Although SSRIs share similar side effect profiles, individual drugs in this class may cause a higher rate or carry a more severe risk of specific side effects depending on the patient.

Sexual Dysfunction. All SSRIs cause sexual dysfunction, and it is the most common adverse effect of SSRIs associated with long-term treatment. It has an estimated incidence of between 50 and 80 percent. The most common complaints are anorgasmia, inhibited orgasm, and decreased libido. Some studies suggest that sexual dysfunction is dose-related, but this has not been established. Unlike most of the other adverse effects of SSRIs, sexual inhibition rarely resolves in the first few weeks of use but usually continues as long as the drug is taken. In some cases, there may be an improvement over time.

Strategies to counteract SSRI-induced sexual dysfunction are numerous, and none has been proven to be very useful. Some reports suggest decreasing the dosage or adding bupropion (Wellbutrin) or amphetamine. Reports have described successful treatment of SSRI-induced sexual dysfunction with agents such as sildenafil (Viagra), which are used to treat erectile dysfunction. Ultimately, patients may need to be switched to antidepressants that do not interfere with sexual functioning, drugs such as mirtazapine or bupropion.

Gastrointestinal Adverse Effects. GI side effects are widespread and are mediated mainly through effects on the serotonin 5-HT$_3$ receptor. The most frequent GI complaints are nausea, diarrhea, anorexia, vomiting, flatulence, and dyspepsia. Sertraline and fluvoxamine produce the most intense GI symptoms. Delayed-release paroxetine, compared with the immediate-release preparation of paroxetine, has less intense GI side effects during the first week of treatment. However, paroxetine, because of its anticholinergic activity, frequently causes constipation. Nausea and loose

stools are usually dose-related and transient, usually resolving within a few weeks. Sometimes flatulence and diarrhea persist, especially during sertraline treatment. Initial anorexia may also occur and is most frequent with fluoxetine. SSRI-induced appetite and weight loss begin as soon as the drug is taken and peak at 20 weeks, after which weight often returns to baseline. Up to one-third of persons taking SSRIs will gain weight, sometimes more than 20 lb. This effect is mediated through a metabolic mechanism, an increase in appetite, or both. It happens gradually and is usually resistant to diet and exercise regimens. Paroxetine is associated with more frequent, rapid, and pronounced weight gain than the other SSRIs, especially among young women.

Cardiovascular Effects. All SSRIs can lengthen the QT interval in otherwise healthy people and cause drug-induced long QT syndrome, especially when taken in overdose. The risk of QTc prolongation increases when an antidepressant and an antipsychotic are used in combination, an increasingly common practice. Citalopram stands out as the SSRI with the most pronounced effect on QT intervals. A QT study to assess the effects of 20- and 60-mg doses of citalopram on the QT interval in adults, compared with placebo, found a maximum mean prolongation in the individually corrected QT intervals were 8.5 milliseconds for 20-mg citalopram and 18.5 milliseconds for 60 mg. For 40 mg, prolongation of the corrected QT interval was estimated to be 12.6 milliseconds. Based on these findings, the FDA has issued the following recommendation regarding citalopram use:

► 20 mg a day is the maximum recommended dose for patients with hepatic impairment, who are older than 60 years of age, who are CYP2C19 poor metabolizers, or who are taking concomitant cimetidine (Tagamet).
► No longer prescribe at doses greater than 40 mg a day.
► Do not use in patients with congenital long QT syndrome.
► Correct hypokalemia and hypomagnesemia before administering citalopram.
► Monitor electrolytes as clinically indicated.

Consider more frequent electrocardiograms in patients with congestive heart failure, bradyarrhythmias, or patients on concomitant medications that

prolong the QT interval.

The fact that citalopram carries a greater risk of causing fatal rhythm abnormalities was confirmed in a review of 469 SSRI poisoning admissions. Accordingly, patients should be advised to contact their prescriber immediately if they experience signs and symptoms of an abnormal heart rate or rhythm while taking citalopram.

The effect of vilazodone (20, 40, 60, and 80 mg) on the QTc interval was evaluated, and a small effect was observed. The upper bound of the 90 percent confidence interval for the largest placebo-adjusted, baseline-corrected QTc interval was below 10 milliseconds, based on the individual correction method (QTcI). This interval is below the threshold for clinical concern. However, it is unknown whether 80 mg is adequate to represent a high clinical exposure condition.

Physicians should consider whether the benefits of androgen deprivation therapy outweigh the potential risks in SSRI treated patients with prostate cancer, as reductions in androgen levels can cause QTc interval prolongation.

Dextromethorphan/Quinidine (Nuedexta) is available as a treatment for pseudobulbar affect, which is defined by involuntary, sudden, and frequent episodes of laughing or crying that are generally out of proportion or inappropriate to the situation. Quinidine can prolong the QT interval and is a potent inhibitor of CYP2D6. It should not be used with other medications that prolong the QT interval and are metabolized by CYP2D6. This drug should be used with caution with any medications that can prolong the QT interval and inhibit CYP3A4, particularly in patients with cardiac disease.

Antepartum use of SSRIs is sometimes associated with QTc interval prolongation in exposed neonates. In a review of 52 newborns exposed to SSRIs in the immediate antepartum period and 52 matched control subjects, the mean QTc was significantly longer in the group of newborns exposed to antidepressants as compared with control subjects. Five (10 percent) newborns exposed to SSRIs had a markedly prolonged QTc interval (greater than 460 milliseconds) compared with none of the unexposed newborns. The most extended QTc interval observed among exposed newborns was 543 milliseconds. All of the drug-associated repolarization abnormalities normalized in subsequent electrocardiographic tracings.

Headaches. The incidence of headache in SSRI trials was 18 to 20 percent,

only one percentage point higher than the placebo rate. Fluoxetine is the most likely to cause headaches. On the other hand, all SSRIs are effective prophylaxis against both migraine and tension-type headaches in many persons.

Central Nervous System Adverse Effects

ANXIETY. Fluoxetine may cause anxiety, particularly in the first few weeks of treatment. However, these initial effects usually give way to an overall reduction in anxiety after a few weeks. Increased anxiety is caused considerably less frequently by paroxetine and escitalopram, which may be better choices if sedation is desired, as in mixed anxiety and depressive disorders.

INSOMNIA AND SEDATION. The primary effect SSRIs exert in the area of insomnia and sedation is improved sleep resulting from the treatment of depression and anxiety. However, as many as 25 percent of persons taking SSRIs note trouble sleeping, excessive somnolence, or overwhelming fatigue. Fluoxetine is the most likely to cause insomnia, for which reason it is often taken in the morning. Sertraline and fluvoxamine are about equally likely to cause insomnia as somnolence, and citalopram and especially paroxetine often cause somnolence. Escitalopram is more likely to interfere with sleep than its isomer, citalopram. Some persons benefit from taking their SSRI dose before going to bed, but others prefer to take it the morning. SSRI-induced insomnia can be treated with benzodiazepines, trazodone (Desyrel) (clinicians must explain the risk of priapism), or other sedating medicines. Significant SSRI-induced somnolence often requires switching to the use of another SSRI or bupropion.

OTHER SLEEP EFFECTS. Many persons taking SSRIs report recalling extremely vivid dreams or nightmares. They describe sleep as "busy." Other sleep effects of the SSRIs include bruxism, restless legs, nocturnal myoclonus, and sweating.

EMOTIONAL BLUNTING. Emotional blunting is a largely overlooked but frequent side effect associated with chronic SSRI use. Patients report an

inability to cry in response to emotional situations, a feeling of apathy or indifference, or a restriction in the intensity of emotional experiences. This side effect often leads to treatment discontinuation, even when the drugs provide relief from depression or anxiety.

YAWNING. Close clinical observation of patients taking SSRIs reveals an increase in yawning. This side effect is not a reflection of fatigue or poor nocturnal sleep but is the result of SSRI effects on the hypothalamus.

SEIZURES. Seizures have been reported in 0.1 to 0.2 percent of all patients treated with SSRIs, an incidence comparable to that reported with other antidepressants and not significantly different from that with placebo. Seizures are more frequent at the highest doses of SSRIs (e.g., fluoxetine 100 mg a day or higher) than at standard doses.

EXTRAPYRAMIDAL SYMPTOMS. The SSRIs may rarely cause akathisia, dystonia, tremor, cogwheel rigidity, torticollis, opisthotonos, gait disorders, and bradykinesia. Rare cases of tardive dyskinesia have been reported. Some people with well-controlled Parkinson disease may experience acute worsening of their motor symptoms when they take SSRIs.

Anticholinergic Effects.
Paroxetine has a mild anticholinergic activity that causes dry mouth, constipation, and sedation in a dose-dependent fashion. Nevertheless, most persons taking paroxetine do not experience cholinergic adverse effects. Other SSRIs are associated with dry mouth, but this effect is not mediated by muscarinic activity.

Hematologic Adverse Effects.
The SSRIs can cause functional impairment of platelet aggregation but not a reduction in platelet number. This pharmacologic effect can manifest through easy bruising and excessive or prolonged bleeding. When patients exhibit these signs, a test for bleeding time should be performed. Special monitoring is suggested when patients use SSRIs in conjunction with anticoagulants or aspirin. Concurrent use of SSRIs and NSAIDs is associated with a significantly increased risk of gastric bleeding. In cases where this combination is necessary, we should consider using proton pump inhibitors.

Electrolyte and Glucose Disturbances. The SSRIs may acutely decrease glucose concentrations; therefore, diabetic patients should be carefully monitored. Long-term use may be associated with increased glucose levels, although it remains to be proven whether this is the result of a pharmacologic effect. Antidepressant users may have other characteristics that raise their odds of developing diabetes, or may be more likely to be diagnosed with diabetes or other medical conditions as a result of being in treatment for depression.

Cases of SSRI-associated hyponatremia and the syndrome of inappropriate antidiuretic hormone have been seen in some patients, especially those who are older or treated with diuretics.

Endocrine and Allergic Reactions. The SSRIs can increase prolactin levels and cause mammoplasia and galactorrhea in both men and women. Breast changes are reversible upon discontinuation of the drug, but this may take several months to occur.

Various types of rashes appear in about 4 percent of all patients; in a small subset of these patients, the allergic reaction may generalize and involve the pulmonary system, rarely resulting in fibrotic damage and dyspnea. SSRI treatment may have to be discontinued in patients with drug-related rashes.

Serotonin Syndrome. Concurrent administration of an SSRI with an MAOI, L-tryptophan, or lithium (Eskalith) can raise plasma serotonin concentrations to toxic levels, producing a constellation of symptoms called *serotonin syndrome*. This severe and possibly fatal syndrome of serotonin overstimulation comprises, in order of appearance as the condition worsens, (1) diarrhea; (2) restlessness; (3) extreme agitation, hyperreflexia, and autonomic instability with possible rapid fluctuations in vital signs; (4) myoclonus, seizures, hyperthermia, uncontrollable shivering, and rigidity; and (5) delirium, coma, status epilepticus, cardiovascular collapse, and death.

Treatment of serotonin syndrome consists of removing the offending agents and promptly instituting comprehensive supportive care. Supportive care and treatment may include nitroglycerine, cyproheptadine (Periactin), methysergide (Sansert), cooling blankets, chlorpromazine (Thorazine), dantrolene (Dantrium), benzodiazepines, anticonvulsants, mechanical ventilation, and paralyzing agents.

Sweating. Some patients experience sweating while being treated with SSRIs. This sweating is independent of the temperature in the environment. Nocturnal sweating may drench bed sheets and require a change of nightclothes. Terazosin (Hytrin), 1 or 2 mg/day, is often dramatically effective in counteracting sweating.

Overdose. The adverse reactions associated with overdose of vilazodone at doses of 200 to 280 mg, as observed in clinical trials, included serotonin syndrome, lethargy, restlessness, hallucinations, and disorientation.

Selective Serotonin Reuptake Inhibitor Withdrawal. The abrupt discontinuance of SSRI use, especially one with a shorter half-life such as paroxetine or fluvoxamine, has been associated with a withdrawal syndrome that may include dizziness, weakness, nausea, headache, rebound depression, anxiety, insomnia, poor concentration, upper respiratory symptoms, paresthesias, and migraine-like symptoms. It usually does not appear until after at least 6 weeks of treatment and usually resolves spontaneously in 3 weeks. Persons who experienced transient adverse effects in the first weeks of taking an SSRI are more likely to experience discontinuation symptoms.

Fluoxetine is the SSRI least likely to be associated with this syndrome because the half-life of its metabolite is more than 1 week, and it effectively tapers itself. Fluoxetine has therefore been used in some cases to treat the discontinuation syndrome caused by the termination of other SSRIs. Nevertheless, a delayed and attenuated withdrawal syndrome occurs with fluoxetine as well.

Drug Interactions

The SSRIs do not interfere with most other drugs. A serotonin syndrome (Table 21-17) can develop with concurrent administration of MAOIs, L-tryptophan, lithium, or other antidepressants that inhibit the reuptake of serotonin. Fluoxetine, sertraline, and paroxetine can raise plasma concentrations of TCAs, which can cause clinical toxicity. Several potential pharmacokinetic interactions have been described based on in vitro analyses of the CYP enzymes, but clinically relevant interactions are rare. SSRIs that inhibit CYP2D6 may interfere with the analgesic effects of hydrocodone and oxycodone. These drugs can also reduce the effectiveness of tamoxifen

(Nolvadex, Soltamox). The combined use of SSRIs and NSAIDs increases the risk of gastric bleeding.

▲	Table 21-17 Serotonin Syndrome Symptoms
Diarrhea	Myoclonus
Diaphoresis	Hyperactive reflexes
Tremor	Disorientation
Ataxia	Lability of mood

The SSRIs, particularly fluvoxamine, should not be used with clozapine because it raises clozapine concentrations, increasing the risk of seizure. The SSRIs may increase the duration and severity of zolpidem (Ambien)-induced side effects, including hallucinations.

Fluoxetine. Fluoxetine can be administered with tricyclic drugs, but the clinician should use low dosages of the tricyclic drug. Because the hepatic enzyme CYP2D6 metabolizes it, fluoxetine may interfere with the metabolism of other drugs in the 7 percent of the population who have an inefficient isoform of this enzyme, the so-called poor metabolizers. Fluoxetine may slow down the metabolism of carbamazepine (Tegretol), antineoplastic agents, diazepam (Valium), and phenytoin (Dilantin). Drug interactions have been described for fluoxetine that may affect the plasma levels of benzodiazepines, antipsychotics, and lithium. Fluoxetine and other SSRIs may interact with warfarin (Coumadin), increasing the risk of bleeding and bruising.

Sertraline. Sertraline may displace warfarin from plasma proteins and may increase the prothrombin time. The drug interaction data on sertraline support a generally similar profile to that of fluoxetine, although sertraline does not interact as strongly with the CYP2D6 enzyme.

Paroxetine. Paroxetine has a higher risk for drug interactions than does either fluoxetine or sertraline because it is a more potent inhibitor of the

CYP2D6 enzyme. Cimetidine can increase the concentration of sertraline and paroxetine, and phenobarbital (Luminal) and phenytoin can decrease the concentration of paroxetine. Because of the potential for interference with the CYP2D6 enzyme, the coadministration of paroxetine with other antidepressants, phenothiazines, and antiarrhythmic drugs should be undertaken with caution. Paroxetine may increase the anticoagulant effect of warfarin. Coadministration of paroxetine and tramadol may precipitate serotonin syndrome in elderly persons.

Fluvoxamine. Among the SSRIs, fluvoxamine appears to present the most risk for drug–drug interactions. Fluvoxamine is metabolized by the enzyme CYP3A4, which may be inhibited by ketoconazole (Nizoral). Fluvoxamine may increase the half-life of alprazolam, triazolam (Halcion), and diazepam, and it should not be coadministered with these agents. Fluvoxamine may increase theophylline levels threefold and warfarin levels twofold, with significant clinical consequences; thus, the serum levels of the latter drugs should be closely monitored, and the doses adjusted accordingly. Fluvoxamine raises concentrations and may increase the activity of clozapine, carbamazepine, methadone (Dolophine, Methadose), propranolol (Inderal), and diltiazem (Cardizem). Fluvoxamine has no significant interactions with lorazepam (Ativan) or digoxin (Lanoxin).

Citalopram. Citalopram is not a potent inhibitor of any CYP enzymes. Concurrent administration of cimetidine increases concentrations of citalopram by about 40 percent. Citalopram does not significantly affect the metabolism of, nor is its metabolism significantly affected by, digoxin, lithium, warfarin, carbamazepine, or imipramine (Tofranil). Citalopram increases the plasma concentrations of metoprolol (Lopressor) twofold, but this usually does not affect BP or heart rate. Data on coadministration of citalopram and potent inhibitors of CYP3A4 or CYP2D6 are not available.

Escitalopram. Escitalopram is a moderate inhibitor of CYP2D6 and has been shown to raise desipramine (Norpramin) and metoprolol concentrations significantly.

Vilazodone. Vilazodone dose should be reduced to 20 mg when

coadministered with CYP3A4 potent inhibitors. Concomitant use with inducers of CYP3A4 can result in inadequate drug concentrations and may diminish effectiveness. The effect of CYP3A4 inducers on the systemic exposure of vilazodone has not been evaluated.

Laboratory Interferences

In general, the SSRIs do not interfere with any laboratory tests. There have been some reports of false-positive urine toxicology for benzodiazepines in patients taking sertraline; if this is suspected, additional confirmation can be sought via gas chromatography-mass spectrometry.

Dosage and Clinical Guidelines

Fluoxetine. Fluoxetine is available in 10- and 20-mg capsules, in a scored 10-mg tablet, as a 90-mg enteric-coated capsule for once-weekly administration, and as an oral concentrate (20 mg/5 mL). Fluoxetine is also marketed as Sarafem for PMDD. For depression, the initial dosage is usually 10 or 20 mg orally each day, usually given in the morning, because insomnia is a potential adverse effect of the drug. Fluoxetine should be taken with food to minimize possible nausea. The long half-lives of the drug and its metabolite contribute to 4 weeks to reach steady-state concentrations. Twenty milligrams is often as effective as higher doses for treating depression. The maximum dosage recommended by the manufacturer is 80 mg a day. To minimize the early side effects of anxiety and restlessness, some clinicians initiate fluoxetine use at 5 to 10 mg a day, either with the scored 10-mg tablet or by using the liquid preparation. Alternatively, because of the long half-life of fluoxetine, its use can be initiated with an every-other-day administration schedule. The dosage of fluoxetine (and other SSRIs) that is effective in other indications may differ from the dosage generally used for depression.

Sertraline. Sertraline is available in scored 25-, 50-, and 100-mg tablets. For the initial treatment of depression, sertraline use should be initiated with a dosage of 50 mg once daily. To limit the GI effects, some clinicians begin at 25 mg a day and increase to 50 mg a day after 3 weeks. Patients who do not respond after 1 to 3 weeks may benefit from dosage increases of 50 mg every week up to a maximum of 200 mg given once daily. Sertraline can be

administered in the morning or in the evening. Administration after eating may reduce the GI adverse effects. Sertraline oral concentrate (1 mL = 20 mg) has 12 percent alcohol content and must be diluted before use. When used to treat panic disorder, sertraline should be initiated at 25 mg to reduce the risk of provoking a panic attack.

Paroxetine. Immediate-release paroxetine is available in scored 20-mg tablets; in unscored 10-, 30-, and 40-mg tablets; and as an orange-flavored 10-mg/5-mL oral suspension. Paroxetine use for the treatment of depression is usually initiated at a dosage of 10 or 20 mg a day. An increase in the dosage should be considered when an adequate response is not seen in 1 to 3 weeks. At that point, the clinician can initiate upward dose titration in 10-mg increments at weekly intervals to a maximum of 50 mg a day. Persons who experience GI upset may benefit from taking the drug with food. Paroxetine can be taken initially as a single daily dose in the evening; higher dosages may be divided into two doses per day.

A delayed-release formulation of paroxetine, paroxetine CR, is available in 12.5-, 25-, and 37.5-mg tablets. The starting dosages of paroxetine CR are 25 mg/day for depression and 12.5 mg/day for panic disorder.

Paroxetine is the SSRI most likely to produce a discontinuation syndrome, because plasma concentrations decrease rapidly in the absence of continuous dosing. Paroxetine use should be tapered gradually to limit the symptoms of abrupt discontinuation, with dosage reductions every 2 to 3 weeks.

Fluvoxamine. Fluvoxamine is the only SSRI not approved by the FDA as an antidepressant. It is indicated for OCD. It is available in unscored 25-mg tablets and scored 50- and 100-mg tablets. The effective daily dosage range is 50 to 300 mg a day. A usual starting dosage is 50 mg once a day at bedtime for the first week, after which the dosage can be adjusted according to the adverse effects and clinical response. Dosages above 100 mg a day may be divided into twice-daily dosing. A temporary dosage reduction or slower upward titration may be necessary if nausea develops over the first 2 weeks of therapy. Although fluvoxamine can also be administered as a single evening dose to minimize its adverse effects, its short half-life may lead to interdose withdrawal. An extended-release formulation is available in 100- and 150-mg dose strengths. All fluvoxamine formulations should be

swallowed with food without chewing the tablet. Abrupt discontinuation of fluvoxamine may cause a discontinuation syndrome owing to its short half-life.

Citalopram. Citalopram is available in 20- and 40-mg scored tablets and as a liquid (10 mg/5 mL). The usual starting dosage is 20 mg a day for the first week, after which it usually is increased to 40 mg a day. For elderly persons or persons with hepatic impairment, 20 mg a day is recommended. Tablets should be taken once daily in either the morning or the evening with or without food.

Escitalopram. Escitalopram is available as 10- and 20-mg scored tablets, as well as an oral solution at a concentration of 5 mg/5 mL. The recommended dosage of escitalopram is 10 mg/day. In clinical trials, no additional benefit was noted when 20 mg/day was used.

Vilazodone. Vilazodone is available as 10-, 20-, and 40-mg tablets. The recommended therapeutic dose of vilazodone is 40 mg once daily. Treatment should be titrated, starting with an initial dose of 10 mg once daily for 7 days, followed by 20 mg once daily for an additional 7 days, and then an increase to 40 mg once daily. Vilazodone should be taken with food. If vilazodone is taken without food, inadequate drug concentrations may result, and the drug's effectiveness may be diminished. Vilazodone is not approved for use in children. The safety and efficacy of vilazodone in pediatric patients have not been studied. The patient's age should not influence the dose, nor does mild or moderate hepatic impairment. Vilazodone has not been studied in patients with severe hepatic impairment. No dose adjustment is recommended in patients with mild, moderate, or severe renal impairment.

Pregnancy and Breastfeeding. Except for paroxetine, the SSRIs are safe to take during pregnancy when deemed necessary for the treatment of the mother. There are no controlled human data regarding vilazodone use during pregnancy, nor are there human data regarding drug concentrations in breast milk. Transient QTc prolongation has been noted in newborns whose mother was being treated with an SSRI during pregnancy.

Loss of Efficacy. Some patients report a diminished response or total loss of response to SSRIs with recurrence of depressive symptoms while remaining on a full dose of medication. The exact mechanism of this so-called "poop-out" is unknown, but the phenomenon is genuine. Potential remedies for the attenuation of the response to SSRIs include increasing or decreasing the dosage, tapering drug use, and then rechallenging with the same medication, switching to another SSRI or non-SSRI antidepressant, and augmenting with bupropion or another augmentation agent.

Vortioxetine (Trintellix). Vortioxetine works mainly as an inhibitor of serotonin (5-HT) reuptake, but it has a more complex pharmacologic profile than other SSRIs. It also acts as an agonist at 5-HT$_{1A}$ receptors, a partial agonist at 5-HT$_{1B}$ receptors, and an antagonist at 5-HT$_3$, 5-HT$_{1D}$, and 5-HT$_7$ receptors. The contribution of each of these activities to the drug's antidepressant effect has not been established, but it is the only compound with this combination of pharmacodynamic actions.

Side effects seen during the trials include, but are not limited to, nausea, constipation, and vomiting.

The recommended starting dose is 10 mg administered orally once daily without regard to meals. The dose should then be increased to 20 mg/day, as tolerated. A dose of 5 mg/day should be considered for patients who do not tolerate higher doses.

The maximum recommended dose of vortioxetine is 10 mg/day in known CYP2D6 poor metabolizers. Reduction of the dose of vortioxetine by one-half is suggested when patients are receiving a CYP2D6 potent inhibitor (e.g., bupropion, fluoxetine, paroxetine, or quinidine) concomitantly. The dose should be increased to the original dose of vortioxetine in patients who stop taking CYP inducers (e.g., rifampin, carbamazepine, or phenytoin). This adjustment is especially essential when a potent CYP inducer is coadministered for greater than 14 days. The maximum recommended dose should not exceed three times the original dose. The dose of vortioxetine should be reduced to the original level within 14 days when the inducer is discontinued.

Although vortioxetine can be abruptly discontinued, in placebo-controlled trials, patients experienced transient adverse reactions such as headache and

muscle tension following abrupt discontinuation of vortioxetine 15 or 20 mg/day. It is recommended that the dose be decreased to 10 mg/day for 1 week before full discontinuation of vortioxetine 15 or 20 mg/day.

Vortioxetine is available in 5-, 10-, 15-, and 20-mg tablets.

SELECTIVE SEROTONIN–NOREPINEPHRINE REUPTAKE INHIBITORS

There are currently four SNRIs approved for use in the United States: venlafaxine (Effexor and Effexor XR), desvenlafaxine succinate (DVS; Pristiq), duloxetine (Cymbalta), and levomilnacipran (Fetzima). A fifth SNRI, milnacipran (Savella), available in other countries as an antidepressant, has U.S. FDA approval in the United States as a treatment for fibromyalgia. The term SNRI reflects the belief that the therapeutic effects of these medications are mediated by concomitant blockade of neuronal serotonin (5-HT) and norepinephrine uptake transporters. The SNRIs are also sometimes referred to as dual reuptake inhibitors, a broader functional class of antidepressant medications that include TCAs such as clomipramine (Anafranil) and, to a lesser extent, imipramine (Tofranil) and amitriptyline (Elavil). What distinguishes the SNRIs from TCAs is their relative lack of affinity for other receptors, especially muscarinic, histaminergic, and the families of α- and β-adrenergic receptors. This distinction is an important one because the SNRIs have a more favorable tolerability profile than the older dual reuptake inhibitors.

Venlafaxine and Desvenlafaxine

Therapeutic Indications. Venlafaxine is approved for the treatment of four disorders: MDD, GAD, social anxiety disorder, and panic disorder. MDD is currently the only FDA-approved indication for DVS.

DEPRESSION. The FDA does not recognize any class of antidepressants as being more effective than any other. This does not mean that differences do not exist, but no study to date has sufficiently demonstrated such superiority. It has been argued that direct modulation of serotonin and norepinephrine may convey more significant antidepressant effects than are exerted by

medications that selectively enhance only noradrenergic or serotoninergic neurotransmission. This more significant therapeutic benefit could result from an acceleration of postsynaptic adaptation to increased neuronal signaling, simultaneous activation of two pathways for intracellular signal transduction, additive effects on the activity of relevant genes such as brain-derived neurotrophic factor, or, quite simply, broader coverage of depressive symptoms. Clinical evidence supporting this hypothesis first emerged in a pair of studies conducted by the Danish University Antidepressant Group, which found an advantage for the dual reuptake inhibitor clomipramine compared with SSRIs citalopram (Celexa) and paroxetine (Paxil). Another report, which compared the results of a group of patients prospectively treated with the combination of desipramine (Norpramin) and fluoxetine (Prozac) with a historical comparison group treated with desipramine alone, provided additional support. A meta-analysis of 25 inpatient studies comparing the efficacy of TCAs and SSRIs yielded the most substantial evidence. Specifically, although the TCAs were found to have a modest overall advantage, superiority versus SSRIs was almost entirely explained by the studies that used the TCAs that are considered to be dual reuptake inhibitors—clomipramine, amitriptyline, and imipramine. Meta-analyses of head-to-head studies suggest that venlafaxine has the potential to induce higher rates of remission in depressed patients than do the SSRIs. This difference in the venlafaxine advantage is about 6 percent. DVS has not been extensively compared with other classes of antidepressants concerning efficacy.

GENERALIZED ANXIETY DISORDER. The extended-release formulation of venlafaxine is approved for the treatment of GAD. In clinical trials lasting 6 months, dosages of 75 to 225 mg a day were effective in treating insomnia, poor concentration, restlessness, irritability, and excessive muscle tension related to GAD.

SOCIAL ANXIETY DISORDER. The extended-release formulation of venlafaxine is approved for the treatment of social anxiety disorder. Its efficacy was established in 12-week studies.

OTHER INDICATIONS. Case reports and uncontrolled studies have indicated that

venlafaxine may be beneficial in the treatment of obsessive-compulsive disorder, panic disorder, agoraphobia, social phobia, ADHD, and patients with a dual diagnosis of depression and cocaine dependence. It has also been used in chronic pain syndromes with good effect.

Precautions and Adverse Reactions. Venlafaxine has a safety and tolerability profile similar to that of the more widely prescribed SSRI class. Nausea is the most frequently reported treatment-emergent adverse effect associated with venlafaxine and DVS therapy. Initiating therapy at lower dosages may also attenuate nausea. When extremely problematic, treatment-induced nausea can be controlled by prescribing a selective 5-HT$_3$ antagonist or mirtazapine (Remeron).

Venlafaxine and DVS therapy is associated with sexual side effects, predominantly decreased libido and a delay to orgasm or ejaculation. The incidence of these side effects may exceed 30 to 40 percent when there is a direct, detailed assessment of sexual function.

Other common side effects include headache, insomnia, somnolence, dry mouth, dizziness, constipation, asthenia, sweating, and nervousness. Although several side effects are suggestive of anticholinergic effects, these drugs have no affinity for muscarinic or nicotinic receptors. Thus, noradrenergic agonism is likely to be the culprit.

Higher-dose venlafaxine therapy is associated with an increased risk of sustained elevations of BP. Experience with the instant-release (IR) formulation in studies of depressed patients indicated that sustained hypertension was dose-related, increasing from 3 to 7 percent at doses of 100 to 300 mg/day and 13 percent at doses greater than 300 mg/day. In this dataset, venlafaxine therapy did not adversely affect BP control of patients taking antihypertensives and lowered the mean values of patients with elevated BP readings before therapy. In controlled studies of the extended-release formulation, venlafaxine therapy resulted in only approximately 1 percent greater risk of high BP when compared with the placebo. Arbitrarily capping the upper dose of venlafaxine used in these studies, thus, significantly attenuated concerns about elevated BP. When higher doses of the extended-release formulation are used, however, monitoring of BP is recommended.

Venlafaxine and DVS are commonly associated with discontinuation

syndrome. This syndrome is characterized by the appearance of a constellation of adverse effects during a rapid taper or abrupt cessation, including dizziness, dry mouth, insomnia, nausea, nervousness, sweating, anorexia, diarrhea, somnolence, and sensory disturbances. It is recommended that, whenever possible, a slow taper schedule should be used when longer-term treatment must be stopped. On occasion, substituting a few doses of the sustained-release formulation of fluoxetine may help to bridge this transition.

There were no overdose fatalities in premarketing trials of venlafaxine, although electrocardiographic changes (e.g., prolongation of QT interval, bundle branch block, QRS interval prolongation), tachycardia, bradycardia, hypotension, hypertension, coma, serotonin syndrome, and seizures were reported. Fatal overdoses have been documented subsequently, typically involving venlafaxine ingestion in combination with other drugs, alcohol, or both.

Information concerning the use of venlafaxine and DVS by pregnant and nursing women is not available at this time. Venlafaxine and DVS are excreted in breast milk. Clinicians should carefully weigh the risks and benefits of venlafaxine use by pregnant and nursing women.

Drug Interactions. Venlafaxine is metabolized in the liver primarily by the CYP2D6 isoenzyme. Because the parent drug and principal metabolite are essentially equipotent, medications that inhibit this isoenzyme usually do not adversely affect therapy. Venlafaxine is itself a relatively weak inhibitor of CYP2D6, although it can increase levels of substrates, such as desipramine or risperidone (Risperdal). In vitro and in vivo studies have shown venlafaxine to cause little or no inhibition of CYP1A2, CYP2C9, CYP2C19, and CYP3A4.

Venlafaxine is contraindicated in patients taking MAOIs because of the risk of a pharmacodynamic interaction (i.e., serotonin syndrome). An MAOI should not be started for at least 7 days after stopping venlafaxine. Few data are available regarding the combination of venlafaxine with atypical neuroleptics, benzodiazepines, lithium (Eskalith), and anticonvulsants; therefore, clinical judgment should be exercised when combining medications.

Laboratory Interferences. Data are not currently available on laboratory

interferences with venlafaxine. There have been some reports of patients taking venlafaxine who have false-positive results on liquid chromatography testing for tramadol.

Dosage and Administration. Venlafaxine is available in 25-, 37.5-, 50-, 75-, and 100-mg tablets and 37.5-, 75-, and 150-mg extended-release capsules. The tablets and the extended-release capsules are equally potent, and persons stabilized with one can switch to an equivalent dosage of the other. Because the immediate-release tablets are rarely used due to their tendency to cause nausea and the need for multiple-daily doses, the dosage recommendations that follow refer to the use of the extended-release capsules.

In depressed persons, venlafaxine demonstrates a dose–response curve. The initial therapeutic dosage is 75 mg a day, given once a day. However, most persons are started at a dosage of 37.5 mg for 4 to 7 days to minimize adverse effects, particularly nausea. A convenient starter kit for the drug contains a 1-week supply of both the 37.5- and 75-mg strengths. If a rapid titration is preferred, the dosage can be raised to 150 mg/day after day 4. As a rule, the dosage can be raised in increments of 75 mg a day every 4 or more days. Although the recommended upper dosage of the extended-release preparation (venlafaxine XR) is 225 mg/day, it is approved by the FDA for use at dosages up to 375 mg a day. The dosage of venlafaxine should be halved in persons with significantly diminished hepatic or renal function. If discontinued, venlafaxine use should be gradually tapered over 2 to 4 weeks to avoid withdrawal symptoms.

There are minor differences in the doses used for major depression, GAD, and social anxiety disorder. In the treatment of these disorders, for example, a dose–response effect has not been found. Also, lower mean dosages are typically used, with most patients taking 75 to 150 mg/day.

DVS is available as 50- and 100-mg extended-release tablets. The therapeutic dose for most patients is 50 mg a day. Although some patients may need higher doses, in clinical trials, no more significant therapeutic benefit was noted when the dose was increased. At higher doses, adverse events and discontinuation rates were increased.

Duloxetine

Pharmacologic Actions. Duloxetine is formulated as a delayed-release capsule to reduce the risk of severe nausea associated with the drug. It is well absorbed, but there is a 2-hour delay before absorption begins. Peak plasma concentrations occur 6 hours after ingestion. Food delays the time to achieve maximum concentrations from 6 to 10 hours and reduces the extent of absorption by about 10 percent. Duloxetine has an elimination half-life of about 12 hours (range, 8 to 17 hours). Steady-state plasma concentrations occur after 3 days. Duloxetine's elimination is mainly through the isozymes CYP2D6 and CYP1A2. Duloxetine undergoes extensive hepatic metabolism to numerous metabolites. About 70 percent of the drug appears in the urine as metabolites, and about 20 percent is excreted in the feces. Duloxetine is 90 percent protein-bound.

Therapeutic Indications

DEPRESSION. In contrast to venlafaxine, a small number of studies have compared duloxetine with the SSRIs. Although these studies are suggestive of some advantage in efficacy, their findings are limited by the use of fixed, low starting doses of paroxetine and fluoxetine, but dosages of duloxetine in some studies were as high as 120 mg/day. Any inferences on whether duloxetine is superior to the SSRIs in any aspect of treatment for depression thus await more evidence from adequately designed trials.

NEUROPATHIC PAIN ASSOCIATED WITH DIABETES AND STRESS URINARY INCONTINENCE. Duloxetine is the first drug to be approved by the FDA as a treatment for neuropathic pain associated with diabetes. Its pain effects have not been compared with other agents, such as venlafaxine and the TCAs. Duloxetine is currently awaiting approval as a treatment for stress urinary incontinence, the inability to voluntarily control bladder voiding, which is the most frequent type of incontinence in women. The action of duloxetine in the treatment of stress urinary incontinence is associated with its effects in the sacral spinal cord, which in turn increases the activity of the striated urethral sphincter. Duloxetine is marketed under the name Yentreve for this indication which has not been approved for this indication in the United States but is available in the European Union and other countries.

PRECAUTIONS AND ADVERSE REACTIONS. The most common adverse reactions are nausea, dry mouth, dizziness, constipation, fatigue, decreased appetite, anorexia, somnolence, and increased sweating. Nausea was the most common side effect that led to treatment discontinuation in clinical trials. The true incidence of sexual dysfunction is unknown; the long-term effects on body weight are also unknown. In clinical trials, treatment with duloxetine was associated with mean increases in BP averaging 2 mm Hg systolic and 0.5 mm Hg diastolic versus placebo. No studies have compared the BP effects of venlafaxine and duloxetine at equivalent therapeutic doses.

Close monitoring is suggested when using duloxetine in patients who have or are at risk for diabetes. Duloxetine has been shown to increase blood sugar and hemoglobin A1C levels during long-term treatment.

Patients with substantial alcohol use should not be treated with duloxetine because of possible hepatic effects. It also should not be prescribed for patients with hepatic insufficiency and end-stage renal disease or patients with uncontrolled narrow-angle glaucoma.

Abrupt discontinuation of duloxetine should be avoided because it may produce a discontinuation syndrome similar to that of venlafaxine. A gradual dose reduction is recommended.

Clinicians should avoid the use of duloxetine by pregnant and nursing women unless the potential benefits justify the potential risks.

Drug Interactions. Duloxetine is a moderate inhibitor of CYP450 enzymes.

Laboratory Interferences. Data are not currently available on laboratory interferences with duloxetine.

Dosage and Administration. Duloxetine is available in 20-, 30-, and 60-mg tablets. The recommended therapeutic and maximum dosage is 60 mg/day. The 20- and 30-mg doses are useful for either initial therapy or for twice-daily use as strategies to reduce side effects. In clinical trials, dosages of up to 120 mg/day were studied, but no consistent advantage in efficacy was noted at doses higher than 60 mg/day. Duloxetine thus does not appear to demonstrate a dosage–response curve. However, there were difficulties in tolerability with single doses above 60 mg. Accordingly, when dosages of 80

and 120 mg/day were used, they were administered as 40 or 60 mg twice daily. It remains to be seen to what extent dosages above 60 mg/day will be necessary and whether this will require divided doses to make the drug tolerable.

Milnacipran and Levomilnacipran

Milnacipran is only FDA approved for the treatment of fibromyalgia. Although some countries have approved milnacipran for general use as an antidepressant, efficacy is not as well established. Compared with venlafaxine, milnacipran is approximately five times more potent for inhibition of norepinephrine uptake than for 5-HT reuptake inhibition. Milnacipran has a half-life of approximately 8 hours and shows linear pharmacokinetics between doses of 50 and 250 mg/day. Milnacipran has no active metabolites, and it is directly metabolized in the liver. The kidneys primarily excrete milnacipran.

Milnacipran is available as 12.5-, 25-, 50-, and 100-mg tablets. The standard recommended milnacipran dose is as follows: day 1, 12.5 mg once daily; days 2 and 3, 12.5 mg twice daily; days 4 to 7, 25 mg twice daily; and day 7 and beyond, 50 mg twice daily.

Levomilnacipran was approved in 2013 by the FDA as a treatment for MDD in adults. Levomilnacipran is an active enantiomer of the racemic drug milnacipran. In vitro studies have shown that it has greater potency for norepinephrine reuptake inhibition than for serotonin reuptake inhibition and does not directly affect the uptake of dopamine or other neurotransmitters. It is taken once daily as a sustained-release formulation. In clinical trials, doses of 40, 80, or 120 mg improved symptoms compared with placebo.

The most common adverse reactions in the placebo-controlled trials were nausea, constipation, hyperhidrosis, increased heart rate, erectile dysfunction, tachycardia, vomiting, and palpitations. Rates of adverse events were generally consistent across the 40- to 120-mg dose range. The only dose-related adverse events were urinary hesitation and erectile dysfunction.

BUPROPION

Bupropion (Wellbutrin, Wellbutrin SR, Wellbutrin XL) is an antidepressant drug that inhibits the reuptake of norepinephrine and, possibly, dopamine.

Most significantly, it does not act on the serotonin system like SSRI antidepressants. This novel action results in a side effect profile characterized by a low risk of sexual dysfunction and sedation and with modest weight loss during acute and long-term treatment. No withdrawal syndrome has been linked to discontinuation of bupropion. Although increasingly used as first-line monotherapy, a significant percentage of bupropion use occurs as add-on therapy to other antidepressants, usually SSRIs. Bupropion was marketed under the name Zyban for use in smoking cessation regimens. However, the manufacturer has discontinued that brand in the United States.

Pharmacologic Actions

Three formulations of bupropion are available: immediate-release (taken three times daily), sustained-release (taken twice daily), and extended-release (taken once daily). The different versions of the drug contain the same active ingredient but differ in their pharmacokinetics and dosing. There have been reports of inconsistencies in bioequivalence between various branded and generic versions of bupropion. If a patient experiences changes in adverse effects or efficacy, the clinician should inquire whether there has been a change of formulation.

Immediate-release bupropion is well absorbed from the GI tract. Peak plasma concentrations of bupropion are usually reached within 2 hours of oral administration, and peak levels of the sustained-release version are seen after 3 hours. The mean half-life of the compound is 12 hours, ranging from 8 to 40 hours. Peak levels of extended-release bupropion occur 5 hours after ingestion. This pharmacokinetic profile provides a longer time to maximum plasma concentration (t_{max}) but comparable peak and trough plasma concentrations. The 24-hour exposure occurring after administration of the extended-release version of 300 mg once daily is equivalent to that provided by sustained release of 150 mg twice daily. Clinically, this permits the drug to be taken once a day in the morning. Plasma levels are also reduced in the evening, making it less likely for some patients to experience treatment-related insomnia.

The mechanism of action for the antidepressant effects of bupropion is presumed to involve the inhibition of dopamine and norepinephrine reuptake. Bupropion binds to the dopamine transporter in the brain. The effects of

bupropion on smoking cessation may be related to its effects on dopamine reward pathways or inhibition of nicotinic acetylcholine receptors.

Therapeutic Indications

Depression. Although overshadowed by the SSRIs as first-line treatment for major depression, the therapeutic efficacy of bupropion in depression is well established in both outpatient and inpatient settings. Observed rates of response and remission are comparable to those seen with the SSRIs. Bupropion has been found to prevent seasonal major depressive episodes in patients with a history of seasonal patterns or affective disorder.

Smoking Cessation. Bupropion is indicated for use in combination with behavioral modification programs for smoking cessation. It is intended to be used in patients who are highly motivated and who receive some form of structured behavioral support. Bupropion is most effective when combined with nicotine substitutes (Nico-Derm, Nicotrol).

Bipolar Disorders. Bupropion is less likely than TCAs to precipitate mania in persons with bipolar I disorder and less likely than other antidepressants to exacerbate or induce rapid-cycling bipolar II disorder; however, the evidence about the use of bupropion in the treatment of patients with bipolar disorder is limited.

Attention-Deficit/Hyperactivity Disorder. Bupropion is used as a second-line agent, after the sympathomimetics, for treatment of ADHD. It has not been compared with proven ADHD medications such as methylphenidate (Ritalin) or atomoxetine (Strattera) for childhood and adult ADHD. Bupropion is an appropriate choice for persons with comorbid ADHD and depression or persons with comorbid ADHD, conduct disorder, or substance use disorder. It may also be considered for use in patients who develop tics when treated with psychostimulants.

Cocaine Detoxification. Bupropion may be associated with a euphoric feeling; thus, it may be contraindicated in persons with histories of substance abuse. However, because of its dopaminergic effects, bupropion has been explored as a treatment for cocaine cravings. Results have been inconclusive,

with some patients showing a reduction in drug craving and others finding their cravings increased.

Hypoactive Sexual Desire Disorder. Bupropion is often added to drugs such as SSRIs to counteract sexual side effects and may be helpful as a treatment for nondepressed individuals with a disorder of sexual desire. Bupropion may improve sexual arousal, orgasm completion, and sexual satisfaction.

Precautions and Adverse Reactions

Headache, insomnia, dry mouth, tremor, and nausea are the most common side effects. Restlessness, agitation, and irritability may also occur. Patients with severe anxiety or panic disorder should not be prescribed bupropion. Most likely, because of its potentiating effects on dopaminergic neurotransmission, bupropion can cause psychotic symptoms, including hallucinations, delusions, and catatonia, as well as delirium. Most notable about bupropion is the absence of significant drug-induced orthostatic hypotension, weight gain, daytime drowsiness, and anticholinergic effects. Some persons, however, may experience dry mouth or constipation and weight loss. Hypertension may occur in some patients, but bupropion causes no other significant cardiovascular or clinical laboratory changes. Bupropion exerts indirect sympathomimetic activity, producing positive inotropic effects in the human myocardium, an effect that may reflect catecholamine release. Some patients experience cognitive impairment, most notably word-finding difficulties.

Concern about seizure has deterred some physicians from prescribing bupropion. The risk of seizure is dose-dependent. Studies show that at dosages of 300 mg a day or less of sustained-
release bupropion, the incidence of seizures is 0.05 percent, which is no worse than the incidence of seizures with other antidepressants. The risk of seizures increases to about 0.1 percent with dosages of 400 mg a day.

Changes in electroencephalographic (EEG) waveforms have been reported to be associated with bupropion use. About 20 percent of individuals treated with bupropion exhibit spike waves, sharp waves, and focal slowing. The likelihood of women having sharp waves is higher than for men. The

presence of these waveforms in individuals taking a medication known to lower the seizure threshold may be a risk factor for developing seizures. Other risk factors for seizures include a history of seizures, use of alcohol, recent benzodiazepine withdrawal, organic brain disease, head trauma, or pretreatment epileptiform discharges on EEG.

The use of bupropion by pregnant women is not associated with a specific risk of an increased rate of congenital disabilities. Bupropion is secreted in breast milk, so the use of bupropion in nursing women should be based on the clinical circumstances of the patient and the judgment of the clinician.

Few deaths have been reported after overdoses of bupropion. Poor outcomes are associated with cases of massive doses and mixed-drug overdoses. Seizures occur in about one-third of all overdoses and are dose-dependent, with those having seizures ingesting a significantly higher median dose. Fatalities can involve uncontrollable seizures, sinus bradycardia, and cardiac arrest. Symptoms of poisoning most often involve seizures, sinus tachycardia, hypertension, GI symptoms, hallucinations, and agitation. All seizures are typically brief and self-limited. In general, however, bupropion is safer in overdose cases than are other antidepressants except for perhaps SSRIs.

Drug Interactions

Given the fact that bupropion is frequently combined with SSRIs or venlafaxine, potential interactions are significant. Bupropion has been found to affect the pharmacokinetics of venlafaxine. One study noted a significant increase in venlafaxine levels and a consequent decrease in its main metabolite O-desmethylvenlafaxine during combined treatment with sustained-release bupropion. Bupropion hydroxylation is weakly inhibited by venlafaxine. No significant changes in plasma levels of the SSRIs paroxetine and fluoxetine have been reported. However, few case reports indicate that the combination of bupropion and fluoxetine (Prozac) may be associated with panic, delirium, or seizures. Bupropion, in combination with lithium (Eskalith), may rarely cause CNS toxicity, including seizures.

Because of the possibility of inducing a hypertensive crisis, bupropion should not be used concurrently with MAOIs. At least 14 days should pass after the discontinuation of an MAOI before initiating treatment with

bupropion. In some cases, the addition of bupropion may permit persons taking antiparkinsonian medications to lower the doses of their dopaminergic drugs. However, delirium, psychotic symptoms, and dyskinetic movements may occur with the coadministration of bupropion and dopaminergic agents, such as antiparkinsonian meds. Sinus bradycardia may occur when bupropion is combined with metoprolol.

Carbamazepine (Tegretol) may decrease plasma concentrations of bupropion, and bupropion may increase plasma concentrations of valproic acid (Depakene).

In vitro biotransformation studies of bupropion have found that the formation of a major active metabolite, hydroxybupropion, is mediated by CYP2B6. Bupropion has a significant inhibitory effect on CYP2D6.

Laboratory Interferences

A report has appeared indicating that bupropion may give a false-positive result on urinary amphetamine screens. No other reports have appeared of laboratory interferences associated with bupropion treatment. Clinically nonsignificant changes in the electrocardiogram (premature beats and nonspecific ST-T changes) and decreases in the WBC count (by about 10 percent) have been reported in a small number of persons.

Dosage and Clinical Guidelines

Immediate-release bupropion is available in 75-, 100-, and 150-mg tablets. Sustained-release bupropion is available in 100-, 150-, 200-, and 300-mg tablets. Extended-release bupropion comes in 150- and 300-mg strengths.

There have been problems associated with one of the extended-release generic versions called Budeprion XL 300-mg tablets, which was found not to be therapeutically equivalent to Wellbutrin XL 300 mg and was removed from the market.

The initiation of immediate-release bupropion in the average adult person should be 75 mg orally twice a day. On the fourth day of treatment, the dosage can be increased to 100 mg three times a day. Because 300 mg is the recommended dose, the person should be maintained on this dose for several weeks before increasing it further. The maximum dosage, 450 mg a day, should be given as 150 mg three times a day. Because of the risk of seizures,

increases in dose should never exceed 100 mg in 3 days; a single dose of immediate-release bupropion should never exceed 150 mg, and the total daily dosage should not exceed 450 mg. The maximum of 400 mg of the sustained-release version should be used as a twice-a-day regimen of either 200 mg twice daily or 300 mg in the morning and 100 mg in the afternoon. A starting dosage of the sustained-release version, 100 mg once a day, can be increased to 100 mg twice a day after 4 days. Then 150 mg twice a day may be used. A single dose of sustained-release bupropion should never exceed 300 mg. The maximum dosage is 200 mg twice a day of the immediate-release or extended-release formulations. An advantage of the extended-release preparation is that the patient can take a single daily dose of 450 mg after proper titration.

For smoking cessation, the patient should start taking 150 mg a day of sustained-release bupropion 10 to 14 days before quitting smoking. On the fourth day, the dosage should be increased to 150 mg twice daily. Treatment generally lasts 7 to 12 weeks.

MIRTAZAPINE

Mirtazapine (Remeron) is unique among drugs used to treat major depression in that it increases both norepinephrine and serotonin through a mechanism other than reuptake blockade (as in the case of tricyclic agents or SSRIs) or monoamine oxidase inhibition (as in the case of phenelzine or tranylcypromine). Mirtazapine is also more likely to reduce rather than cause nausea and diarrhea, the result of its effects on serotonin 5-HT_3 receptors. Characteristic side effects include increased appetite and sedation.

Pharmacologic Actions

Mirtazapine is administered orally and is rapidly and completely absorbed. It has a half-life of about 30 hours. Peak concentration is achieved within 2 hours of ingestion, and steady state is reached after 6 days. Plasma clearance may be slowed up to 30 percent in persons with impaired hepatic function, up to 50 percent in those with impaired renal function, up to 40 percent slower in older men, and up to 10 percent slower in older women.

The mechanism of action of mirtazapine is the antagonism of central

presynaptic α_2-adrenergic receptors and blockade of postsynaptic serotonin 5-HT$_2$ and 5-HT$_3$ receptors. The α_2-adrenergic receptor antagonism causes the increased firing of norepinephrine and serotonin neurons. The potent antagonist of serotonin 5-HT$_2$ and 5-HT$_3$ receptors serves to decrease anxiety, relieve insomnia, and stimulate the appetite. Mirtazapine is a potent antagonist of histamine H$_1$ receptors and is a moderately potent antagonist at α_1-adrenergic and muscarinic-cholinergic receptors.

Therapeutic Indications

Mirtazapine is effective for the treatment of depression. It is highly sedating, making it a reasonable choice for use in depressed patients with severe or long-standing insomnia. Some patients find the residual daytime sedation associated with the initiation of treatment to be quite pronounced. However, the more extreme sedating properties of the drug generally lessen over the first week of treatment. Combined with the tendency to sometimes cause a ravenous appetite, mirtazapine is well suited for depressed patients with melancholic features such as insomnia, weight loss, and agitation. Elderly depressed patients, in particular, are good candidates for mirtazapine; young adults are more likely to object to this side effect profile.

Mirtazapine's blockade of 5-HT$_3$ receptors, a mechanism associated with medications used to combat the severe GI side effects of cancer chemotherapy agents, has led to the use of the drug in a similar role. In this population, sedation and stimulation of appetite clearly could be seen as being beneficial instead of unwelcome side effects.

Mirtazapine is often combined with SSRIs or venlafaxine to augment antidepressant response or counteract serotonergic side effects of those drugs, particularly nausea, agitation, and insomnia. Mirtazapine has no significant pharmacokinetic interactions with other antidepressants.

Precautions and Adverse Reactions

Somnolence, the most common adverse effect of mirtazapine, occurs in more than 50 percent of persons (Table 21-18). Persons starting mirtazapine should thus exercise caution when driving or operating dangerous machinery and even when getting out of bed at night. This adverse effect is why mirtazapine

is almost always given before sleep. Mirtazapine potentiates the sedative effects of other CNS depressants, so potentially sedating prescription or over-the-counter drugs and alcohol should be avoided during the use of mirtazapine. Mirtazapine also causes dizziness in 7 percent of persons. It does not appear to increase the risk of seizures. Mania or hypomania occurred in clinical trials at a rate similar to that of other antidepressant drugs.

Mirtazapine increases appetite in about one-third of patients. Mirtazapine may also increase serum cholesterol concentration to 20 percent or more above the upper limit of normal in 15 percent of persons and increase triglycerides to 500 mg/dL or more in 6 percent of persons. Elevations of alanine transaminase levels to more than three times the upper limit of normal were seen in 2 percent of mirtazapine-treated persons as opposed to 0.3 percent of placebo control subjects.

In limited premarketing experience, the absolute neutrophil count dropped to 500/mm^3 or less within 2 months of the onset of use in 0.3 percent of persons, some of whom developed symptomatic infections. This hematologic condition was reversible in all cases and was more likely to occur when other risk factors for neutropenia were present. Increases in the frequency of neutropenia have not, however, been reported during the extensive postmarketing period. Persons who develop fever, chills, sore throat, mucous membrane ulceration, or other signs of infection should nevertheless be evaluated medically. If a low WBC count is found, mirtazapine should be immediately discontinued, and the infectious disease status should be followed closely.

Table 21-18
Adverse Reactions Reported with Mirtazapine

Event	Patients (%)
Somnolence	54
Dry mouth	25
Increased appetite	17
Constipation	13

Weight gain	12
Dizziness	7
Myalgias	5
Disturbing dreams	4

A small number of persons experience orthostatic hypotension while taking mirtazapine. Although no data exist regarding the effects on fetal development, mirtazapine should be used with caution during pregnancy.

Mirtazapine use by pregnant women has not been studied, but because the drug may be excreted in breast milk, it should not be taken by nursing mothers. Because of the risk of agranulocytosis associated with mirtazapine use, persons should be attuned to signs of infection. Because of the sedating effects of mirtazapine, persons should determine the degree to which they are affected before engaging in driving or other potentially dangerous activities.

Drug Interactions

Mirtazapine can potentiate the sedation of alcohol and benzodiazepines. Mirtazapine should not be used within 14 days of use of an MAOI.

Laboratory Interferences

No laboratory interferences have yet been described for mirtazapine.

Dosage and Administration

Mirtazapine is available in 15-, 30-, and 45-mg scored tablets. Mirtazapine is also available in 15-, 30-, and 45-mg orally disintegrating tablets for persons who have difficulty swallowing pills. If persons fail to respond to the initial dose of 15 mg of mirtazapine before sleep, the dose may be increased in 15-mg increments every 5 days to a maximum of 45 mg before sleep. Lower dosages may be necessary for elderly persons or persons with renal or hepatic insufficiency.

NEFAZODONE AND TRAZODONE

Nefazodone (Serzone) and Trazodone (Desyrel) are mechanistically and

structurally related drugs approved as treatments for depression. Nefazodone (Serzone) is an analog of trazodone. When nefazodone was introduced in 1995, there were expectations that it would become widely used because it did not cause the sexual side effects and sleep disruption associated with the selective SSRIs. Although it was devoid of these side effects, it was nevertheless found to produce problematic sedation, nausea, dizziness, and visual disturbances. Consequently, nefazodone was never extensively adopted in clinical practice. This fact, as well as reports of rare cases of sometimes fatal hepatotoxicity, led the original manufacturer to discontinue the production of branded nefazodone in 2004. Generic nefazodone remains available in the United States.

Trazodone received FDA approval in 1981 as a treatment for MDD. Its novel triazolopyridine chemical structure distinguished it from the TCAs, and clinical trials suggested improved safety and tolerability compared with TCAs. There were high expectations that it would replace the older drugs as a mainstay of treatment for depression. However, the extreme sedation associated with trazodone, even at subtherapeutic doses, limited the clinical effectiveness of the drug. However, its soporific properties made trazodone a favorite alternative to standard hypnotics as a sleep-inducing agent. Unlike conventional sleeping pills, trazodone is not a controlled substance.

Nefazodone

Pharmacologic Actions. Nefazodone is rapidly and completely absorbed but is then extensively metabolized so that the bioavailability of active compounds is about 20 percent of the oral dose. Its half-life is 2 to 4 hours. Steady-state concentrations of nefazodone and its principal active metabolite, hydroxynefazodone, are achieved within 4 to 5 days. Metabolism of nefazodone in elderly persons, especially women, is about half of that seen in younger persons, so lowered doses are recommended for elderly persons. An important metabolite of nefazodone is meta-chlorophenylpiperazine (mCPP), which has some serotonergic effects and may cause migraine, anxiety, and weight loss.

Although nefazodone is an inhibitor of serotonin uptake and, more weakly, of norepinephrine reuptake, its antagonism of serotonin $5-HT_A$ receptors is thought to produce its antianxiety and antidepressant effects. Nefazodone is

also a mild antagonist of the α_1-adrenergic receptors, which predisposes some persons to orthostatic hypotension but is not sufficiently potent to produce priapism.

Therapeutic Indications. Nefazodone is effective for the treatment of major depression. The usual effective dosage is 300 to 600 mg a day. In direct comparison with SSRIs, nefazodone is less likely to cause inhibition of orgasm or decreased sexual desire. Nefazodone is also effective for the treatment of panic disorder and panic with comorbid depression or depressive symptoms, GAD, and PMDD and management of chronic pain. It is not useful for the treatment of OCD. Nefazodone increases rapid eye movement (REM) sleep and increases sleep continuity. Nefazodone is also of use in patients with PTSD and chronic fatigue syndrome. It may also be effective in patients who have been treatment-resistant to other antidepressant drugs.

Precautions and Adverse Reactions. The most common reasons for discontinuing nefazodone use are sedation, nausea, dizziness, insomnia, weakness, and agitation (Table 21-19). Many patients report no specific side effects but describe a vague sense of feeling medicated. Nefazodone also causes visual trails, in which patients see an afterimage when looking at moving objects or when moving their heads quickly.

A significant safety concern with the use of nefazodone is a severe elevation of hepatic enzymes, and, in some instances, liver failure. Accordingly, serial hepatic function tests need to be done when patients are treated with nefazodone. Hepatic effects can be seen early in treatment and are more likely to develop when nefazodone is combined with other drugs metabolized in the liver.

Some patients taking nefazodone may experience a decrease in BP that can cause episodes of postural hypotension. Nefazodone should therefore be used with caution by persons with underlying cardiac conditions or history of stroke or heart attack, dehydration, or hypovolemia or by persons being treated with antihypertensive medications. Patients switched from SSRIs to nefazodone may experience an increase in side effects, possibly because nefazodone does not protect against SSRI withdrawal symptoms. One of its metabolites, mCPP, may intensify these discontinuation symptoms. Patients have survived nefazodone overdoses above 10 g, but deaths have been

reported when it has been combined with alcohol. Nausea, vomiting, and somnolence are the most common signs of toxicity.

Table 21-19
Adverse Reactions Reported with Nefazodone (300–600 mg a day)

Reaction	Patients (%)
Headache	36
Dry mouth	25
Somnolence	25
Nausea	22
Dizziness	17
Constipation	14
Insomnia	11
Weakness	11
Lightheadedness	10
Blurred vision	9
Dyspepsia	9
Infection	8
Confusion	7
Scotomata	7

There are few studies or clinical reports of nefazodone during pregnancy. Nefazodone should, therefore, be used during pregnancy only if the potential benefit to the mother outweighs the potential risks to the fetus. It is not known whether nefazodone is excreted in human breast milk. Therefore, it should be used with caution by lactating mothers. The nefazodone dosage should be lowered in persons with severe hepatic disease, but no adjustment

is necessary for persons with renal disease.

Drug Interactions and Laboratory Interferences. Nefazodone should not be given concomitantly with MAOIs. Also, nefazodone has particular drug–drug interactions with the triazolobenzodiazepines triazolam (Halcion) and alprazolam (Xanax) because of the inhibition of CYP3A4 by nefazodone. Potentially elevated levels of each of these drugs can develop after administration of nefazodone, but the levels of nefazodone are generally not affected. The dose of triazolam should be lowered by 75 percent, and the dose of alprazolam should be lowered by 50 percent, when given concomitantly with nefazodone.

Nefazodone may slow the metabolism of digoxin; therefore, digoxin levels should be monitored carefully in persons taking both medications. Nefazodone also slows the metabolism of haloperidol (Haldol) so that the dosage of haloperidol should be reduced in persons taking both medications. The addition of nefazodone may also exacerbate the adverse effects of lithium carbonate (Eskalith).

There are no known laboratory interferences associated with nefazodone.

Dosage and Clinical Guidelines. Nefazodone is available in 50-, 200-, and 250-mg unscored tablets and 100- and 150-mg scored tablets. The recommended starting dosage of nefazodone is 100 mg twice a day, but 50 mg twice a day may be better tolerated, especially by elderly persons. The dosage should be slowly raised in increments of 100 to 200 mg a day at intervals of no less than 1 week per increase to limit the development of adverse effects. The optimal dosage is 300 to 600 mg daily in two divided doses. However, some studies report that nefazodone is effective when taken once a day, especially at bedtime. Geriatric persons should receive dosages about two-thirds of the usual nongeriatric dosages, with a maximum of 400 mg a day. Similar to other antidepressants, the clinical benefit of nefazodone usually appears after 2 to 4 weeks of treatment. Patients with the premenstrual syndrome are treated with a flexible dosage that averages about 250 mg a day.

Trazodone

Pharmacologic Actions. Trazodone is readily absorbed from the GI tract and reaches peak plasma levels in about 1 hour. It has a half-life of 5 to 9 hours. Trazodone is metabolized in the liver, and 75 percent of its metabolites are excreted in the urine.

Trazodone is a weak inhibitor of serotonin reuptake and a potent antagonist of serotonin 5-HT_{2A} and 5-HT_{2C} receptors. The active metabolite of trazodone is mCPP, which is an agonist at 5-HT_{2C} receptors and has a half-life of 14 hours. mCPP has been associated with migraine, anxiety, and weight loss. The adverse effects of trazodone are partially mediated by α_1-adrenergic receptor antagonism.

Therapeutic Indications

DEPRESSIVE DISORDERS. The main indication for the use of trazodone is MDD. There is a dose–response relationship, with dosages of 250 to 600 mg a day being necessary for trazodone to have therapeutic benefit. Trazodone increases total sleep time, decreases the number and the duration of nighttime awakenings, and decreases the amount of REM sleep. Unlike tricyclic drugs, trazodone does not decrease stage 4 sleep. Trazodone is thus useful for depressed persons with anxiety and insomnia.

INSOMNIA. Trazodone is a first-line agent for the treatment of insomnia because of its marked sedative qualities and favorable effects on sleep architecture (see above) combined with its lack of anticholinergic effects. Trazodone is effective for insomnia caused by depression or the use of drugs. When used as a hypnotic, the usual initial dosage is 25 to 100 mg at bedtime.

ERECTILE DISORDER. Trazodone is associated with an increased risk of priapism. Trazodone can potentiate erections resulting from sexual stimulation. It has thus been used to prolong erectile time and turgidity in some men with erectile disorder. The dosage for this indication is 150 to 200 mg a day. Trazodone-triggered priapism (an erection lasting more than 3 hours with pain) is a medical emergency. The use of trazodone for the treatment of male erectile dysfunction has diminished considerably since the introduction of phosphodiesterase (PDE)-5 agents (see Chapter 16).

OTHER INDICATIONS. Trazodone may be useful in low dosages (50 mg a day) for controlling severe agitation in children with developmental disabilities and elderly persons with dementia. At dosages above 250 mg a day, trazodone reduces the tension and apprehension associated with GAD. It has been used to treat depression in patients with schizophrenia. Trazodone may have a beneficial effect on insomnia and nightmares in persons with PTSD.

Precautions and Adverse Reactions. The most common adverse effects associated with trazodone are sedation, orthostatic hypotension, dizziness, headache, and nausea. Some persons experience dry mouth or gastric irritation. The drug is not associated with anticholinergic adverse effects, such as urinary retention, weight gain, and constipation. A few case reports have noted an association between trazodone and arrhythmias in persons with preexisting premature ventricular contractions or mitral valve prolapse. Neutropenia, usually not of clinical significance, may develop, which should be considered if persons have a fever or sore throat.

Trazodone may cause significant orthostatic hypotension 4 to 6 hours after a dose is taken, especially if taken concurrently with antihypertensive agents or if a large dose is taken without food. Administration of trazodone with food slows absorption and reduces the peak plasma concentration, thus reducing the risk of orthostatic hypotension.

Because suicide attempts often involve the ingestion of sleeping pills, it is essential to be familiar with the symptoms and treatment of trazodone overdose. Patients have survived trazodone overdoses of more than 9 g. Symptoms of overdose include lethargy, vomiting, drowsiness, headache, orthostasis, dizziness, dyspnea, tinnitus, myalgias, tachycardia, incontinence, shivering, and coma. Treatment consists of emesis or lavage and supportive care. Forced diuresis may enhance elimination. Treat hypotension and sedation as appropriate.

Trazodone causes priapism, prolonged erection in the absence of sexual stimuli, in one of every 10,000 men. Trazodone-induced priapism usually appears in the first 4 weeks of treatment but may occur as late as 18 months into treatment. It can appear at any dose. In such cases, trazodone use should be discontinued, and another antidepressant should be used. Painful erections or erections lasting more than 1 hour are warning signs that warrant immediate discontinuation of the drug and medical evaluation. The first step

in the emergency management of priapism is an intracavernosal injection of an α_1-adrenergic agonist pressor agent, such as metaraminol (Aramine) or epinephrine. In about one-third of reported cases, surgical intervention was required. In some cases, permanent impairment of erectile function or impotence resulted.

The use of trazodone is contraindicated in pregnant and nursing women. Trazodone should be used with caution in persons with hepatic and renal diseases.

Drug Interactions. Trazodone potentiates the CNS depressant effects of other centrally acting drugs and alcohol. Concurrent use of trazodone and antihypertensives may cause hypotension. No cases of hypertensive crisis have been reported when trazodone has been used to treat MAOI-associated insomnia. Trazodone can increase levels of digoxin and phenytoin. Trazodone should be used with caution in combination with warfarin. Drugs that inhibit CYP3A4 can increase levels of trazodone's primary metabolite, mCPP, leading to an increase in side effects.

Laboratory Interferences. No known laboratory interferences are associated with the administration of trazodone.

Dosage and Clinical Guidelines. Trazodone is available in 50-, 100-, 150-, and 300-mg tablets. Once-a-day dosing is as effective as divided dosing and reduces daytime sedation. The usual starting dose is 50 mg before sleep. The dosage can be increased in increments of 50 mg every 3 days if sedation or orthostatic hypotension does not become a problem. The therapeutic range for trazodone is 200 to 600 mg a day in divided doses. Some reports indicate that dosages of 400 to 600 mg a day are required for maximal therapeutic effects; other reports indicate that 250 to 400 mg a day is sufficient. The dosage may be titrated up to 300 mg a day; then, the person can be evaluated for the need for further dosage increases based on the presence or the absence of signs of clinical improvement.

TRICYCLICS AND TETRACYCLICS

The observation in 1957 that imipramine (Tofranil) had antidepressant effects

led to the development of a new class of antidepressant compounds, the tricyclics (TCAs). In turn, the finding that imipramine blocked reuptake of norepinephrine led to research into the role of catecholamines in depression. After the introduction of imipramine, several other antidepressant compounds were developed that shared a basic tricyclic structure and had relatively similar effects. Later, other heterocyclic compounds were also marketed that were somewhat similar in structure and that had relatively comparable secondary properties. At one time, amitriptyline (Elavil, Endep) and imipramine were the two most commonly prescribed antidepressants in the United States. However, because of their anticholinergic and antihistaminic side effects, they are rarely used for depression. Nortriptyline (Aventyl, Pamelor) and desipramine (Norpramin, Pertofrane) became preferred. Nortriptyline has the least effect on orthostatic hypotension, and desipramine is the least anticholinergic. Although introduced as antidepressants, the therapeutic indications for these agents have grown to include panic disorder, GAD, PTSD, OCD, and pain syndromes. The introduction of newer antidepressant agents with more selective actions on neurotransmitters or with unique mechanisms of action has sharply reduced the prescribing of TCAs and tetracyclics. The improved safety profiles of the newer drugs, especially when taken in overdose, also contributed to the decline in the use of older drugs. Nevertheless, the TCAs and tetracyclics remain unsurpassed in terms of their antidepressant efficacy. Table 21-20 lists TCA and tetracyclic drugs and their available preparations.

Pharmacologic Actions

The absorption of most TCAs is complete after oral administration, and there is significant metabolism from the first-pass effect. Peak plasma concentrations occur within 2 to 8 hours, and the half-lives of the TCAs vary from 10 to 70 hours; nortriptyline, maprotiline (Ludiomil), and particularly protriptyline (Vivactil) can have longer half-lives. The long half-lives allow all the compounds to be given once daily; 5 to 7 days is needed to reach steady-state plasma concentrations. Imipramine pamoate (Tofranil) is a depot form of the drug for intramuscular (IM) administration; indications for the use of this preparation are limited.

The TCAs undergo hepatic metabolism by the CYP450 enzyme system.

Clinically relevant drug interactions may result from competition for enzyme CYP2D6 among TCAs and quinidine, cimetidine (Tagamet), fluoxetine (Prozac), sertraline (Zoloft), paroxetine (Paxil), phenothiazines, carbamazepine (Tegretol), and the type IC antiarrhythmics propafenone (Rythmol) and flecainide (Tambocor). Concomitant administration of TCAs and these inhibitors may slow down the metabolism and raise the plasma concentrations of TCAs. Additionally, genetic variations in the activity of CYP2D6 may account for up to a 40-fold difference in plasma TCA concentrations in different persons. The dosage of the TCA may need to be adjusted to correct changes in the rate of hepatic TCA metabolism.

Table 21-20
Tricyclic and Tetracyclic Drug Preparations

Drug	Tablets (mg)	Capsules (mg)	Parenteral (mg/mL)	Solution
Imipramine (Tofranil)	10, 25, and 50	75, 100, 125, and 150	12.5	—
Desipramine (Norpramin, Pertofrane)	10, 25, 50, 75, 100, and 150	—	—	—
Trimipramine (Surmontil)	—	25, 50, and 100	—	—
Amitriptyline (Elavil)	10, 25, 50, 75, 100, and 150	—	10	—
Nortriptyline (Aventyl, Pamelor)	—	10, 25, 50, and 75	—	10 mg/5 mL
Protriptyline (Vivactil)	5 and 10	—	—	—
Amoxapine (Asendin)	25, 50, 100, and 150	—	—	—
Doxepin (Sinequan)	—	10, 25, 50, 75, 100, and 150	—	10 mg/mL
Maprotiline (Ludiomil)	25, 50, and 75	—	—	—
Clomipramine (Anafranil)	—	25, 50, and 75	—	—

The TCAs block the transporter site for norepinephrine and serotonin, thus increasing synaptic concentrations of these neurotransmitters. Each drug differs in its affinity for each of these transporters, with clomipramine (Anafranil) being the most serotonin selective and desipramine the most norepinephrine selective of the TCAs. Secondary effects of the TCAs include antagonism at the muscarinic acetylcholine, histamine H_1, and α_1- and α_2-adrenergic receptors. The potency of these effects on other receptors largely determines the side effect profile of each drug. Amoxapine, nortriptyline, desipramine, and maprotiline have the least anticholinergic activity; doxepin has the most antihistaminergic activity. Although they are more likely to cause constipation, sedation, dry mouth, or lightheadedness than the SSRIs, the TCAs are less prone to cause sexual dysfunction, significant long-term

weight gain, and sleep disturbances than the SSRIs. The half-lives and plasma clearance for most TCAs are very similar.

Therapeutic Indications

The indications are similar to those for the SSRIs, which have widely replaced the TCAs. However, the TCAs represent a reasonable alternative for persons who cannot tolerate the adverse effects of the SSRIs.

Major Depressive Disorder. The treatment of a major depressive episode and the prophylactic treatment of MDD are the principal indications for using TCAs. Although the TCAs are effective in the treatment of depression in persons with bipolar I disorder, they are more likely to induce mania, hypomania, or cycling than the newer antidepressants, most notably the SSRIs and bupropion. It is thus not advised that TCAs be routinely used to treat depression associated with bipolar I or bipolar II disorder.

Melancholic features, prior major depressive episodes, and a family history of depressive disorders increase the likelihood of therapeutic response. All of the available TCAs are equally effective in the treatment of depressive disorders. In the case of a person, however, one tricyclic or tetracyclic may be useful, and another one may be ineffective. The treatment of a major depressive episode with psychotic features almost always requires the coadministration of an antipsychotic drug and an antidepressant.

Although it is used worldwide as an antidepressant, clomipramine is only approved in the United States for the treatment of OCD.

Panic Disorder with Agoraphobia. Imipramine is the TCA most studied for panic disorder with agoraphobia, but other TCAs are also useful when taken at the usual antidepressant dosages. Because of the potential initial anxiogenic effects of the TCAs, starting dosages should be small, and the dosage should be titrated upward slowly. Small doses of benzodiazepines may be used initially to deal with this side effect.

Generalized Anxiety Disorder. The FDA approves the use of doxepin for the treatment of anxiety disorders. Some research data show that imipramine may also be useful. Although rarely used anymore, a chlordiazepoxide–amitriptyline combination (Limbitrol) is available for mixed anxiety and

depressive disorders.

Obsessive-Compulsive Disorder. Patients with OCD appear to respond specifically to clomipramine, as well as the SSRIs. Some improvement is usually seen in 2 to 4 weeks, but a further reduction in symptoms may continue for the first 4 to 5 months of treatment. None of the other TCAs appears to be nearly as effective as clomipramine for the treatment of this disorder. Clomipramine may also be a drug of choice for depressed persons with marked obsessive features.

Pain. The TCAs are widely used to treat chronic neuropathic pain and in the prophylaxis of migraine headache. Amitriptyline is the TCA most often used in this role. During the treatment of pain, doses are generally lower than those used in depression; for example, 75 mg of amitriptyline may be sufficient. These effects also appear more rapidly.

Other Disorders. Childhood enuresis is often treated with imipramine. Peptic ulcer disease can be treated with doxepin, which has marked antihistaminergic effects. Other indications for the TCAs are narcolepsy, nightmare disorder, and PTSD. The drugs are sometimes used for the treatment of children and adolescents with ADHD, sleepwalking disorder, separation anxiety disorder, and sleep terror disorder. Clomipramine has also been used to treat premature ejaculation, movement disorders, and compulsive behavior in children with autistic disorders; however, because the TCAs have caused sudden death in several children and adolescents, they should not be used in children.

Precautions and Adverse Reactions

The TCAs are associated with a wide range of problematic side effects and can be lethal when taken in overdose.

Psychiatric Effects. The TCAs can induce a switch to mania or hypomania in susceptible individuals. The TCAs may also exacerbate psychotic disorders in susceptible persons. At high plasma concentrations (levels above 300 ng/mL), the anticholinergic effects of the TCAs can cause confusion or delirium. Patients with dementia are particularly vulnerable to

this development.

Anticholinergic Effects. Anticholinergic effects often limit the tolerable dosage to relatively low ranges. Some persons may develop a tolerance for the anticholinergic effects with continued treatment. Anticholinergic effects include dry mouth, constipation, blurred vision, delirium, and urinary retention. Sugarless gum, candy, or fluoride lozenges can alleviate dry mouth. Bethanechol (Urecholine), 25 to 50 mg three or four times a day, may reduce urinary hesitancy and may be helpful in erectile dysfunction when the drug is taken 30 minutes before sexual intercourse. Anticholinergic drugs can also aggravate narrow-angle glaucoma, and the precipitation of glaucoma requires emergency treatment with a miotic agent. The TCAs should be avoided in persons with narrow-angle glaucoma, and an SSRI should be substituted. Severe anticholinergic effects can lead to CNS anticholinergic syndrome. This syndrome includes symptoms of confusion and delirium, especially if the TCAs are administered with DRAs or anticholinergic drugs. IM or IV physostigmine (Antilirium, Eserine) is used to diagnose and treat anticholinergic delirium.

Cardiac Effects. When administered in their usual therapeutic dosages, the TCAs may cause tachycardia, flattened T waves, prolonged QT intervals, and depressed ST segments in the electrocardiographic (ECG) recording. Imipramine has a quinidine-like effect at therapeutic plasma concentrations and may reduce the number of premature ventricular contractions. Because the drugs prolong conduction time, their use in persons with preexisting conduction defects is contraindicated. In persons with a history of any type of heart disease, the TCAs should be used only after SSRIs or other newer antidepressants have been found ineffective, and if used, they should be introduced at low dosages, with gradual increases in dosage and monitoring of cardiac functions. All of the TCAs can cause tachycardia, which may persist for months and is one of the most common reasons for drug discontinuation, especially in younger persons. At high plasma concentrations, as seen in overdoses, the drugs become arrhythmogenic.

Other Autonomic Effects. Orthostatic hypotension is the most common cardiovascular autonomic adverse effect, and the most common reason TCAs

are discontinued. It can result in falls and injuries in affected persons. Nortriptyline may be the drug least likely to cause this problem. Orthostatic hypotension is treated with avoidance of caffeine, intake of at least 2 L of fluid per day, and addition of salt to the diet unless the person is being treated for hypertension. In persons taking antihypertensive agents, reduction of the dosage may reduce the risk of orthostatic hypotension. Other possible autonomic effects are profuse sweating, palpitations, and increased BP. Although some persons respond to fludrocortisone (Florinef), 0.02 to 0.05 mg twice a day, the drug has potential toxicities. It is preferable to substitute an SSRI than to use a mineralocorticoid such as fludrocortisone. The TCAs' use should be discontinued several days before elective surgery because of the occurrence of hypertensive episodes during surgery in persons receiving TCAs.

Sedation. Sedation is a common effect of the TCAs and may be welcomed if sleeplessness has been a problem. The sedative effect of the TCAs is a result of anticholinergic and antihistaminergic activities. Amitriptyline, trimipramine, and doxepin are the most sedating agents; imipramine, amoxapine, nortriptyline, and maprotiline are less sedating; and desipramine and protriptyline are the least sedating agents.

Neurologic Effects. A fine, rapid tremor may occur. Myoclonic twitches and tremors of the tongue and the upper extremities are common. Rare effects include speech blockage, paresthesia, peroneal palsies, and ataxia.

Amoxapine is unique in causing parkinsonian symptoms, akathisia, and even dyskinesia because of the dopaminergic blocking activity of one of its metabolites. Amoxapine may also cause neuroleptic malignant syndrome in rare cases. Maprotiline may cause seizures when the dosage is increased too quickly or is kept at high levels for too long. Clomipramine and amoxapine may lower the seizure threshold more than other drugs in the class. As a class, however, the TCAs have a relatively low risk for inducing seizures except in persons who are at risk for seizures (e.g., persons with epilepsy and those with brain lesions). Although such persons can still use the TCAs, the initial dosages should be lower than usual, and subsequent dosage increases should be gradual.

Allergic and Hematologic Effects. Exanthematous rashes are seen in 4 to 5 percent of all persons treated with maprotiline. Jaundice is rare. Agranulocytosis, leukocytosis, leukopenia, and eosinophilia are rare complications of TCA treatment. However, a person who has a sore throat or a fever during the first few months of TCA treatment should have a CBC done immediately.

Hepatic Effects. Mild and self-limited increases in serum transaminase concentrations may occur and should be monitored. The TCAs can also produce a fulminant acute hepatitis in 0.1 to 1 percent of persons. This side effect can be life-threatening, and the antidepressant should be discontinued.

Other Adverse Effects. Modest weight gain is typical. Amoxapine exerts a DRA effect and may cause hyperprolactinemia, impotence, galactorrhea, anorgasmia, and ejaculatory disturbances. Other TCAs have also been associated with gynecomastia and amenorrhea. The syndrome of inappropriate secretion of antidiuretic hormone has also been reported with TCAs. Other effects include nausea, vomiting, and hepatitis.

TERATOGENICITY AND PREGNANCY-RELATED RISKS. A definitive link between the tricyclic compounds and tetracyclic compounds and teratogenic effects has not been established, but isolated reports of morphogenesis have been reported. TCAs cross the placenta, and neonatal drug withdrawal can occur. This syndrome includes tachypnea, cyanosis, irritability, and poor sucking reflex. If possible, tricyclic and tetracyclic medications should be discontinued 1 week before delivery. Recently, norepinephrine and serotonin transporters have been identified in the placenta. They appear to play an essential role in the clearance of these amines in the fetus. The understanding of the effects of reuptake inhibitors on these transporters during pregnancy is limited. However, one study compared intelligence and language development in 80 children exposed to TCAs during pregnancy with 84 children exposed to other nonteratogenic agents and found no deleterious effects of the TCAs. The TCAs are excreted in breast milk at concentrations similar to plasma. The actual quantity delivered, however, is small, so drug levels in the infant are usually undetectable or very low. Because the risk of relapse is a serious concern in patients with recurrent depression, and these

risks may be increased during pregnancy or the postpartum period, the risks and benefits of continuing or withdrawing treatment need to be discussed with the patient and weighed carefully.

Precautions. The TCAs may cause a withdrawal syndrome in newborns consisting of tachypnea, cyanosis, irritability, and poor sucking reflex. The drugs do pass into breast milk but at concentrations that are usually undetectable in the infant's plasma. We should use these drugs cautiously in patients with hepatic or renal diseases. The TCAs should not be administered during a course of ECT, primarily because of the risk of serious adverse cardiac effects.

Drug Interactions

Monoamine Oxidase Inhibitors. The TCAs should not be taken within 14 days of administration of an MAOI.

Antihypertensives. The TCAs block the therapeutic effects of antihypertensive medication. The TCAs may block the antihypertensive effects of the β-adrenergic receptor antagonists (e.g., propranolol [Inderal] and clonidine [Catapres]). The coadministration of a TCA and α-methyldopa (Aldomet) may cause behavioral agitation.

Antiarrhythmic Drugs. The antiarrhythmic properties of TCAs can be additive to those of quinidine, an effect that is further exacerbated by the inhibition of TCA metabolism by quinidine.

Dopamine Receptor Antagonists. Concurrent administration of TCAs and DRAs increases the plasma concentrations of both drugs. Desipramine plasma concentrations may increase twofold during concurrent administration with perphenazine (Trilafon). The DRAs also add to the anticholinergic and sedative effects of the TCAs. Concomitant use of SDAs also increases those effects.

Central Nervous System Depressants. Opioids, alcohol, anxiolytics, hypnotics, and over-the-counter cold medications have additive effects by causing CNS depression when coadministered with TCAs. Persons should be

advised to avoid driving or using dangerous equipment if sedated by TCAs.

Sympathomimetics. Tricyclic drug use with sympathomimetic drugs may cause serious cardiovascular effects.

Oral Contraceptives. Birth control pills may decrease TCA plasma concentrations through the induction of hepatic enzymes.

Other Drug Interactions. Nicotine may reduce TCA concentrations. Plasma concentrations may also be lowered by ascorbic acid, ammonium chloride, barbiturates, cigarette smoking, carbamazepine, chloral hydrate, lithium (Eskalith), and primidone (Mysoline). TCA plasma concentrations may be increased by concurrent use of acetazolamide (Diamox), sodium bicarbonate, acetylsalicylic acid, cimetidine, thiazide diuretics, fluoxetine, paroxetine, and fluvoxamine (Luvox). Plasma concentrations of the TCAs may rise three- to fourfold when administered concurrently with fluoxetine, fluvoxamine, and paroxetine.

Laboratory Interferences

The tricyclic compounds are present at low concentrations and are not likely to interfere with other laboratory assays. They may interfere with the determination of conventional neuroleptic blood concentrations because of their structural similarity and the low concentrations of some neuroleptics.

Dosage and Clinical Guidelines

Persons who intend to take TCAs should undergo routine physical and laboratory examinations, including a CBC, a WBC count with differential, and serum electrolytes with liver function tests. An ECG should be obtained for all persons, especially women older than 40 years of age and men older than 30 years of age. The TCAs are contraindicated in persons with a QT_c greater than 450 milliseconds. The initial dose should be small and should be raised gradually. Because of the availability of highly effective alternatives to TCAs, a newer agent should be used if there is any medical condition that may interact adversely with the TCAs.

Elderly persons and children are more sensitive to TCA adverse effects

than are young adults. In children, the ECG should be regularly monitored during the use of a TCA.

The available preparations of TCAs are presented in Table 21-20. The dosages and therapeutic blood levels for the TCAs vary among the drugs (Table 21-21). Except for protriptyline, all of the TCAs should be started at 25 mg a day and increased as tolerated. Divided doses at first reduce the severity of the adverse effects, although most of the dosage should be given at night to help induce sleep if a sedating drug such as amitriptyline is used. Eventually, the entire daily dose can be given at bedtime. A common clinical mistake is to stop increasing the dosage when the person is tolerating the drug but taking less than the maximum therapeutic dose and does not show clinical improvement. The clinician should routinely assess the person's pulse and orthostatic changes in BP while the dosage is being increased.

Nortriptyline use should be started at 25 mg a day. Most patients need only 75 mg a day to achieve a blood level of 100 mg/nL. However, the dosage may be raised to 150 mg a day if needed. Amoxapine use should be started at 150 mg a day and raised to 400 mg a day. Protriptyline use should be started at 15 mg a day and raised to 60 mg a day. Maprotiline has been associated with an increased incidence of seizures. This risk is most significant if the dosage is raised too quickly or is maintained at too high a level. Maprotiline use should be started at 25 mg a day and increased over 4 weeks to 225 mg a day. It should be kept at that level for only 6 weeks and then be reduced to 175 to 200 mg a day.

Persons with chronic pain may be particularly sensitive to adverse effects when TCA use is started. Therefore, treatment should begin with low dosages that are raised in small increments. However, persons with chronic pain may experience relief on long-term low-dosage therapy, such as amitriptyline or nortriptyline at 10 to 75 mg a day.

Table 21-21
General Information for the Tricyclic and Tetracyclic Antidepressants

Generic Name	Trade Name	Usual Adult Dosage Range (mg/day)	Therapeutic Plasma Concentrations (µg/mL)

Imipramine	Tofranil	150–300	150–300[a]
Desipramine	Norpramin, Pertofrane	150–300	150–300[a]
Trimipramine	Surmontil	150–300	150–300
Amitriptyline	Elavil, Endep	150–300	100–250[b]
Nortriptyline	Pamelor, Aventyl	50–150	50–150[a] (maximum)
Protriptyline	Vivactil	15–60	75–250
Amoxapine	Asendin	150–400	200–500[c]
Doxepin	Adapin, Sinequan	150–300	100–250[a]
Maprotiline	Ludiomil	150–230	150–300[a]
Clomipramine	Anafranil	130–250	50 to 250[c]

[a]Exact range may vary among laboratories.
[b]Includes parent compound and desmethyl metabolite.
[c]Estimated from limited studies.

The TCAs should be avoided in children except as a last resort. Dosing guidelines in children for imipramine include initiation at 1.5 mg/kg a day. The dosage can be titrated to no more than 5 mg/kg a day. In enuresis, the dosage is usually 50 to 100 mg a day, taken at bedtime. Clomipramine use can be initiated at 50 mg a day and increased to no more than 3 mg/kg per day or 200 mg a day.

When TCA treatment is discontinued, the dosage should first be decreased to three-fourths the maximal dosage for a month. At that time, if no symptoms are present, drug use can be tapered by 25 mg (5 mg for protriptyline) every 4 to 7 days. Slow tapering avoids a cholinergic rebound syndrome consisting of nausea, upset stomach, sweating, headache, neck pain, and vomiting. This syndrome can be treated by reinstituting a small dosage of the drug and tapering more slowly than before. Several case reports note the appearance of rebound mania or hypomania after the abrupt

discontinuation of TCA use.

Plasma Concentrations and Therapeutic Drug Monitoring.

Clinical determinations of plasma concentrations should be conducted after 5 to 7 days on the same dosage of medication and 8 to 12 hours after the last dose. Because of variations in absorption and metabolism, there may be a 30- to 50-fold difference in the plasma concentrations in persons given the same dosage of a TCA. Nortriptyline is unique in its association with a therapeutic window—that is, plasma concentrations below 50 ng/mL or above 150 ng/mL may reduce its efficacy.

Plasma concentrations may be useful in confirming compliance, assessing reasons for drug failures, and documenting effective plasma concentrations for future treatment. Clinicians should always treat the person and not the plasma concentration. Some persons have adequate clinical responses with seemingly subtherapeutic plasma concentrations, and other persons only respond at supratherapeutic plasma concentrations without experiencing adverse effects. The latter situation, however, should alert the clinician to monitor the person's condition with, for example, serial ECG recordings.

Overdose Attempts. Overdose attempts with TCAs are severe and can often be fatal. Prescriptions for these drugs should be nonrefillable and for no longer than 1 week at a time for patients at risk for suicide. Amoxapine may be more likely than the other TCAs to result in death when taken in overdose. The newer antidepressants are safer in overdose.

Symptoms of overdose include agitation, delirium, convulsions, hyperactive deep tendon reflexes, bowel and bladder paralysis, dysregulation of BP and temperature, and mydriasis. The patient then progresses to coma and perhaps respiratory depression. Cardiac arrhythmias may not respond to treatment. Because of the long half-lives of TCAs, the patients are at risk of cardiac arrhythmias for 3 to 4 days after the overdose, so they should be monitored in intensive care medical settings.

MONOAMINE OXIDASE INHIBITORS

Introduced in the late 1950s, MAOIs were the first class of approved antidepressant drugs. The first of these drugs, isoniazid, was intended to be

used as a treatment for tuberculosis, but its antidepressant properties were discovered by chance when some treated patients experienced elevation of mood during treatment. Despite their effectiveness, prescription of MAOIs as first-line agents has always been limited by concern about the development of potentially lethal hypertension and the consequent need for a restrictive diet. The use of MAOIs declined further after the introduction of the SSRIs and other new agents. They are now mainly relegated to use in treatment-resistant cases. Thus, the second-line status of MAOIs has less to do with considerations of efficacy than with safety concerns. The currently available MAOIs include phenelzine (Nardil), isocarboxazid (Marplan), tranylcypromine (Parnate), rasagiline (Azilect), moclobemide (Manerix), and selegiline (Eldepryl).

Two subsequent advances in the field of antidepressant MAOIs involve the introduction of a selective reversible inhibitor of MAO_A (RIMA), moclobemide (Manerix), in the early 1990s into most countries except the United States, and in 2005, the introduction of a transdermal delivery form of selegiline (Emsam) in the United States that is used for the treatment of parkinsonism. Other RIMA agents, including brofaromine (Consonar) and befloxatone, have not been submitted for registration despite favorable outcomes in clinical trials.

Pharmacologic Actions

Phenelzine, tranylcypromine, and isocarboxazid are readily absorbed after oral administration and reach peak plasma concentrations within 2 hours. Whereas their plasma half-lives are in the range of 2 to 3 hours, their tissue half-lives are considerably longer. Because they irreversibly inactivate MAOs, the therapeutic effect of a single dose of irreversible MAOIs may persist for as long as 2 weeks. The RIMA moclobemide is rapidly absorbed and has a half-life of 0.5 to 3.5 hours. Because it is a reversible inhibitor, moclobemide has a much briefer clinical effect after a single dose than do irreversible MAOIs.

The MAO enzymes are found on the outer membranes of mitochondria, where they degrade cytoplasmic and extraneuronal monoamine neurotransmitters such as norepinephrine, serotonin, dopamine, epinephrine, and tyramine. MAOIs act in the CNS, the sympathetic nervous system, the

liver, and the GI tract. There are two types of MAOs, MAO_A and MAO_B. MAO_A primarily metabolizes norepinephrine, serotonin, and epinephrine; both MAO_A and MAO_B metabolize dopamine and tyramine.

The structures of phenelzine and tranylcypromine are similar to those of amphetamine and have similar pharmacologic effects in that they increase the release of dopamine and norepinephrine with attendant stimulant effects on the brain.

Therapeutic Indications

MAOIs are used for the treatment of depression. Some research indicates that phenelzine is more effective than TCAs in depressed patients with mood reactivity, extreme sensitivity to interpersonal loss or rejection, prominent anergia, hyperphagia, and hypersomnia—a constellation of symptoms conceptualized as atypical depression. Evidence also suggests that MAOIs are more effective than TCAs as a treatment for bipolar depression.

Patients with panic disorder and social phobia respond well to MAOIs. MAOIs have also been used to treat bulimia nervosa, PTSD, anginal pain, atypical facial pain, migraine, ADHD, idiopathic orthostatic hypotension, and depression associated with traumatic brain injury.

Precautions and Adverse Reactions

The most frequent adverse effects of MAOIs are orthostatic hypotension, insomnia, weight gain, edema, and sexual dysfunction. Orthostatic hypotension can lead to dizziness and falls. Thus, cautious upward tapering of the dosage should be used to determine the maximum tolerable dosage. Treatment for orthostatic hypotension includes avoidance of caffeine; intake of 2 L of fluid per day; addition of dietary salt or adjustment of antihypertensive drugs (if applicable); support stockings; and in severe cases, treatment with fludrocortisone (Florinef), a mineralocorticoid, 0.1 to 0.2 mg a day. Orthostatic hypotension associated with tranylcypromine use can usually be relieved by dividing the daily dosage.

Insomnia can be treated by dividing the dose, not giving the medication after dinner, and using a benzodiazepine hypnotic if necessary. Weight gain, edema, and sexual dysfunction often do not respond to any treatment and may warrant switching to another agent. When switching from one MAOI to

another, the clinician should taper and stop the use of the first drug for 10 to 14 days before beginning the use of the second drug.

Paresthesias, myoclonus, and muscle pains are occasionally seen in persons treated with MAOIs. Paresthesias may be secondary to MAOI-induced pyridoxine deficiency, which may respond to supplementation with pyridoxine, 50 to 150 mg orally each day. Occasionally, persons complain of feeling drunk or confused, perhaps indicating that the dosage should be reduced and then increased gradually. Reports that the hydrazine MAOIs are associated with hepatotoxic effects are relatively uncommon. MAOIs are less cardiotoxic and less epileptogenic than are the tricyclic and tetracyclic drugs.

The most common adverse effects of the RIMA moclobemide are dizziness, nausea, and insomnia or sleep disturbance. RIMAs cause fewer GI adverse effects than do SSRIs. Moclobemide does not have adverse anticholinergic or cardiovascular effects, and it has not been reported to interfere with sexual function.

MAOIs should be used with caution by persons with renal disease, cardiovascular disease, or hyperthyroidism. MAOIs may alter the dosage of a hypoglycemic agent required by persons with diabetes. MAOIs have been significantly associated with the induction of mania in persons in the depressed phase of bipolar I disorder and triggering a psychotic decompensation in persons with schizophrenia. MAOIs are contraindicated during pregnancy, although data on their teratogenic risk are minimal. Nursing women should not take MAOIs because the drugs can pass into breast milk.

Tyramine-Induced Hypertensive Crisis. The most worrisome side effect of MAOIs is the tyramine-induced hypertensive crisis. The amino acid tyramine is usually transformed via GI metabolism. However, MAOIs inactivate GI metabolism of dietary tyramine, thus allowing intact tyramine to enter the circulation. A hypertensive crisis may subsequently occur as a result of a powerful pressor effect of the amino acid. Tyramine-containing foods should be avoided for 2 weeks after the last dose of an irreversible MAOI to allow the resynthesis of adequate concentrations of MAO enzymes.

Accordingly, foods rich in tyramine (Table 21-22) or other sympathomimetic amines, such as ephedrine, pseudoephedrine (Sudafed), or dextromethorphan (Trocal), should be avoided by persons who are taking

irreversible MAOIs. Patients should be advised to continue the dietary restrictions for 2 weeks after they stop MAOI treatment to allow the body to resynthesize the enzyme. Bee stings may cause a hypertensive crisis. In addition to severe hypertension, other symptoms may include headache, stiff neck, diaphoresis, nausea, and vomiting. A patient with these symptoms should seek immediate medical treatment.

Table 21-22
Tyramine-Rich Foods to Be Avoided in Planning Monoamine Oxidase Inhibitor Diets

High Tyramine Content[a] (≥2 mg of tyramine a serving)
- Cheese: English Stilton, blue cheese, white (3 yr old), extra old, old cheddar, Danish blue, mozzarella, cheese snack spreads
- Fish, cured meats, sausage; pâtés and organs, salami, mortadella, air-dried sausage
- Alcoholic beverages[b]: Liqueurs and concentrated after-dinner drinks
- Marmite (concentrated yeast extract)
- Sauerkraut (Krakus)

Moderate Tyramine Content[a] (0.5–1.99 mg of tyramine a serving)
- Cheese: Swiss Gruyere, muenster, feta, parmesan, gorgonzola, blue cheese dressing, Black Diamond
- Fish, cured meats, sausage, pâtés and organs: Chicken liver (5 days old); bologna; aged sausage, smoked meat; salmon mousse
- Alcoholic beverages: Beer and ale (12 oz per bottle)—Amstel, Export Draft, Blue Light, Guinness Extra Stout, Old Vienna, Canadian, Miller Light, Export, Heineken, Blue Wines (per 4-oz glass)—Rioja (red wine)

Low Tyramine Content[a] (0.01 to >0.49 mg of tyramine a serving)
- Cheese: Brie, Camembert, Cambozola with or without rind
- Fish, cured meat, sausage, organs, and pâtés; pickled herring; smoked fish; kielbasa sausage; chicken liver; liverwurst (<2 days old)
- Alcoholic beverages: Red wines, sherry, scotch[c]

[a]Any food left out to age or spoil can spontaneously develop tyramine through fermentation.

[b]Alcohol can produce profound orthostasis interacting with monoamine oxidase inhibitors (MAOIs) but cannot produce direct hypotensive reactions.

[c]White wines, gin, and vodka have no tyramine content.

Table by Jonathan M. Himmelhoch, M.D.

An MAOI-induced hypertensive crisis should be treated with α-adrenergic antagonists—for example, phentolamine (Regitine) or chlorpromazine (Thorazine). These drugs lower BP within 5 minutes. IV furosemide (Lasix) can be used to reduce fluid load, and a β-adrenergic receptor antagonist can control tachycardia. A sublingual 10-mg dose of nifedipine (Procardia) can be given and repeated after 20 minutes. Persons with thyrotoxicosis or pheochromocytoma should not use MAOIs.

The risk of tyramine-induced hypertensive crises is relatively low for persons who are taking RIMAs, such as moclobemide and befloxatone. These drugs have relatively little inhibitory activity for MAO_B, and because they are reversible, regular activity of existing MAO_A returns within 16 to 48 hours of the last dose of a RIMA. Therefore, the dietary restrictions are less stringent for RIMAs, applying only to foods containing high concentrations of tyramine, which need to be avoided for 3 days after the last dose of a RIMA. A reasonable dietary recommendation for persons taking RIMAs is to avoid eating tyramine-containing foods 1 hour before and 2 hours after taking a RIMA.

Spontaneous, nontyramine-induced hypertensive crisis is a rare occurrence, usually shortly after the first exposure of an MAOI. Persons experiencing such a crisis should avoid MAOIs altogether.

Withdrawal. Abrupt cessation of regular doses of MAOIs may cause a self-limited discontinuation syndrome consisting of arousal, mood disturbances, and somatic symptoms. Dosages should be gradually tapered over several weeks to avoid these symptoms.

Overdose. It often takes 1 to 6 hours after an overdose for the toxic symptoms to occur. MAOI overdose is characterized by agitation that can progress to coma with hyperthermia, hypertension, tachypnea, tachycardia,

dilated pupils, and hyperactive deep tendon reflexes. Involuntary movements may be present, particularly in the face and the jaw. Acidification of the urine markedly hastens the excretion of MAOIs, and dialysis can be of some use. Phentolamine or chlorpromazine may be useful if hypertension is a problem. Moclobemide alone in overdosage causes relatively mild and reversible symptoms.

Drug Interactions

The significant drug–drug interactions involving MAOIs are listed in Table 21-23. Most antidepressants, as well as precursor agents, should be avoided. Persons should be instructed to tell any other physicians or dentists who are treating them that they are taking an MAOI. MAOIs may potentiate the action of CNS depressants, including alcohol and barbiturates. MAOIs should not be coadministered with serotonergic drugs, such as SSRIs and clomipramine (Anafranil), because this combination can trigger serotonin syndrome. The use of lithium or tryptophan with an irreversible MAOI may also induce serotonin syndrome. Initial symptoms of serotonin syndrome can include tremor, hypertonicity, myoclonus, and autonomic signs, which can then progress to hallucinosis, hyperthermia, and even death. Fatal reactions had occurred when MAOIs were combined with meperidine (Demerol) or fentanyl (Sublimaze).

Table 21-23
Drugs to Be Avoided during Monoamine Oxidase Inhibitor Treatment (Partial Listing)

Never Use
 Antiasthmatics
 Antihypertensives (methyldopa, guanethidine, reserpine)
 Buspirone
 Levodopa
 Opioids (especially meperidine, dextromethorphan, propoxyphene, tramadol; morphine or codeine may be less dangerous)
 Cold, allergy, or sinus medications containing dextromethorphan

or sympathomimetics
SSRIs, clomipramine, venlafaxine, sibutramine
Sympathomimetics (amphetamines, cocaine, methylphenidate, dopamine, epinephrine, norepinephrine, isoproterenol, ephedrine, pseudoephedrine, phenylpropanolamine)
L-Tryptophan

Use Carefully
Anticholinergics
Antihistamines
Disulfiram
Bromocriptine
Hydralazine
Sedative-hypnotics
Terpin hydrate with codeine
Tricyclics and tetracyclics (avoid clomipramine)

SSRI, selective serotonin reuptake inhibitor.

When switching from an irreversible MAOI to any other type of antidepressant drug, persons should wait at least 14 days after the last dose of the MAOI before beginning the use of the next drug to allow replenishment of the body's MAOs. When switching from an antidepressant to an irreversible MAOI, persons should wait 10 to 14 days (or 5 weeks for fluoxetine [Prozac]) before starting the use of the MAOI to avoid drug–drug interactions. In contrast, MAO activity recovers completely 24 to 48 hours after the last dose of a RIMA.

The effects of the MAOIs on hepatic enzymes are poorly studied. Tranylcypromine inhibits CYP2C19. Moclobemide inhibits CYP2D6, CYP2C19, and CYP1A2 and is a substrate for 2C19.

Cimetidine (Tagamet) and fluoxetine significantly reduce the elimination of moclobemide. Modest doses of fluoxetine and moclobemide administered concurrently may be well tolerated, with no significant pharmacodynamic or pharmacokinetic interactions.

Laboratory Interferences

MAOIs may lower blood glucose concentrations. MAOIs artificially raise

urinary metanephrine concentrations and may cause a false-positive test result for pheochromocytoma or neuroblastoma. MAOIs have been reported to be associated with a minimal false elevation in thyroid function test results.

Dosage and Clinical Guidelines

There is no definitive rationale for choosing one irreversible MAOI over another. Table 21-24 lists MAOI preparations and typical dosages. Phenelzine use should begin with a test dose of 15 mg on the first day. The dosage can be increased to 15 mg three times daily during the first week and increased by 15 mg a day each week after that until the dosage of 90 mg a day, in divided doses, is reached by the end of the fourth week. Tranylcypromine and isocarboxazid use should begin with a test dosage of 10 mg and may be increased to 10 mg three times daily by the end of the first week. Many clinicians and researchers have recommended upper limits of 50 mg a day for isocarboxazid and 40 mg a day for tranylcypromine. Administration of tranylcypromine in multiple small daily doses may reduce its hypotensive effects.

Table 21-24
Typical Dosage Forms and Recommended Dosages for Currently Available Monoamine Oxidase Inhibitors

Drug	Usual Dose (mg/day)	Maximum Dose (mg/day)	Dosage (Oral) Formulation
Isocarboxazid (Marplan)	20–40	60	10-mg tablets
Phenelzine (Nardil)	30–60	90	15-mg tablets
Tranylcypromine (Parnate)	20–60	60	10-mg tablets
Rasagiline	0.5–1.0	1.0	0.5- or 1.0-mg tablets
Selegiline	10	30	5-mg tablets

(Eldepryl)			
Moclobemide (Manerix)	300–600	600	100- or 150-mg tablets

Even though coadministration of MAOIs with TCAs, SSRIs, or lithium is generally contraindicated, these combinations have been used successfully and safely to treat patients with refractory depression. However, they should be used with extreme caution.

Hepatic transaminase serum concentrations should be monitored periodically because of the potential for hepatotoxicity, especially with phenelzine and isocarboxazid. Elderly persons may be more sensitive to MAOI adverse effects than are younger adults. MAO activity increases with age, so MAOI dosages for elderly persons are the same as those required for younger adults. We know little about using MAOIs in children.

Studies have suggested that transdermal selegiline has antidepressant properties. Although selegiline is a type B inhibitor at low doses, it becomes less selective as the dose is increased.

THYROID HORMONES

Thyroid hormones—levothyroxine (Synthroid, Levothroid, Levoxine) and liothyronine (Cytomel)—are used in psychiatry either alone or as an augmentation to treat persons with depression or rapid-cycling bipolar I disorder. They can convert an antidepressant-nonresponsive person into an antidepressant-responsive person. Thyroid hormones are also used as replacement therapy for persons treated with lithium (Eskalith) who have developed a hypothyroid state. Successful use of thyroid hormone as an intervention for treatment-resistant patients was first reported in the early 1970s. Study results since then have been mixed; however, most show that patients taking triiodothyronine (T_3) are twice as likely to respond to antidepressant treatment versus placebo. These studies have found that augmentation with T_3 is significant with TCAs and SSRIs. Nevertheless, many endocrinologists object to the use of thyroid hormones as antidepressant augmentation agents, citing such risks as osteoporosis and cardiac arrhythmias.

Pharmacologic Actions

Thyroid hormones are administered orally, and their absorption from the GI tract is variable. Absorption is increased if the drug is administered on an empty stomach. Thyroxine (T_4) crosses the blood–brain barrier and diffuses into neurons, where it is converted into T_3, which is the physiologically active form. The half-life of T_4 is 6 to 7 days, and that of T_3 is 1 to 2 days.

The mechanism of action for thyroid hormone effects on antidepressant efficacy is unknown. Thyroid hormone binds to intracellular receptors that regulate the transcription of a wide range of genes, including several receptors for neurotransmitters.

Therapeutic Indications

The primary indication for thyroid hormones in psychiatry is as an adjuvant to antidepressants. There is no clear correlation between the laboratory measures of thyroid function and the response to thyroid hormone supplementation of antidepressants. If a patient has not responded to a 6-week course of antidepressants at appropriate dosages, adjuvant therapy with either lithium or a thyroid hormone is an alternative. Most clinicians use adjuvant lithium before trying a thyroid hormone. Several controlled trials have indicated that liothyronine use converts about 50 percent of antidepressant nonresponders to responders.

The dosage of liothyronine is 25 or 50 µg a day added to the patient's antidepressant regimen. Liothyronine has been used primarily as an adjuvant for tricyclic drugs; however, evidence suggests that liothyronine augments the effects of all of the antidepressant drugs.

Thyroid hormones have not been shown to cause particular problems in pediatric or geriatric patients; however, the hormones should be used with caution in elderly persons who may have occult heart disease.

Precautions and Adverse Reactions

At the dosages usually used for augmentation—25 to 50 µg a day—adverse effects occur infrequently. The most common adverse effects associated with thyroid hormones are transient headache, weight loss, palpitations, nervousness, diarrhea, abdominal cramps, sweating, tachycardia, increased

BP, tremors, and insomnia. Osteoporosis may also occur with long-term treatment, but this has not been found in studies involving liothyronine augmentation. Overdoses of thyroid hormones can lead to cardiac failure and death.

Patients with cardiac disease, angina, or hypertension should not take thyroid hormones. The hormones are contraindicated in thyrotoxicosis and uncorrected adrenal insufficiency and persons with acute myocardial infarctions. Thyroid hormones can be administered safely to pregnant women, provided that laboratory thyroid indexes are monitored. Thyroid hormones are minimally excreted in breast milk and have not been shown to cause problems in nursing babies.

Drug Interactions

Thyroid hormones can potentiate the effects of warfarin (Coumadin) and other anticoagulants by increasing the catabolism of clotting factors. They may increase the insulin requirement for diabetic persons and the digitalis requirement for persons with cardiac disease. We should not coadminister with sympathomimetics, ketamine (Ketalar), or maprotiline (Ludiomil) because of the risk of cardiac decompensation. Administration of SSRIs, tricyclic and tetracyclic drugs, lithium, or carbamazepine (Tegretol) can mildly lower serum T_4 and raise serum thyrotropin concentrations in euthyroid persons or persons taking thyroid replacements. This interaction warrants close serum monitoring and may require an increase in the dosage or initiation of thyroid hormone supplementation.

Laboratory Interferences

Levothyroxine has not been reported to interfere with any laboratory test other than thyroid function indexes. Liothyronine, however, suppresses the release of endogenous T_4, thereby lowering the result of any thyroid function test that depends on the measure of T_4.

Thyroid Function Tests

Several thyroid function tests are available, including tests for T_4 by competitive protein binding (T_4 [D]) and by radioimmunoassay (T_4 RIA)

involving a specific antigen–antibody reaction. More than 90 percent of T_4 is bound to serum protein and is responsible for thyroid-stimulating hormone (TSH) secretion and cellular metabolism. Other thyroid measures include the free T_4 index (FT_4I), T_3 uptake, and total serum T_3 measured by radioimmunoassay (T_3 RIA). Those tests are used to rule out hypothyroidism, which can be associated with symptoms of depression. In some studies, up to 10 percent of patients complaining of depression and associated fatigue had an incipient hypothyroid disease. Lithium can cause hypothyroidism and, more rarely, hyperthyroidism. Neonatal hypothyroidism results in intellectual disability and is preventable if the diagnosis is made at birth.

Thyrotropin-Releasing Hormone Stimulation Test. The thyrotropin-releasing hormone (TRH) stimulation test is indicated for patients who have marginally abnormal thyroid test results with suspected subclinical hypothyroidism, which may account for clinical depression. It is also used in patients with possible lithium-induced hypothyroidism. The procedure entails an intravenous injection of 500 mg of protirelin (TRH), which produces a sharp increase in serum TSH levels are measured at 15, 30, 60, and 90 minutes. An increase in serum TSH of 5 to 25 mIU/mL above the baseline is normal. An increase of less than 7 mIU/mL is considered a blunted response, which may correlate with a diagnosis of depression. Eight percent of all patients with depression have some thyroid illness.

Dosage and Clinical Guidelines

Liothyronine is available in 5-, 25-, and 50-µg tablets. Levothyroxine is available in 12.5-, 25-, 50-, 75-, 88-, 100-, 112-, 125-, 150-, 175-, 200-, and 300-µg tablets; it is also available in a 200 and 500 µg parenteral form. The dosage of liothyronine is 25 or 50 µg a day added to the person's antidepressant regimen. Liothyronine has been used as an adjuvant for all of the available antidepressant drugs. An adequate trial of liothyronine supplementation should last 2 to 3 weeks. If liothyronine supplementation is successful, it should be continued for 2 months and then tapered off at a rate of 12.5 µg a day every 3 to 7 days.

NOVEL AGENTS

Several agents with novel mechanisms are currently approved for use. They are usually given in specialized centers, and clinicians should only administer after special training to manage their significant safety profile.

NMDA Receptor Antagonists

Ketamine, an anesthetic agent, is used in specialized centers for depression. It has a unique action, as after a single low dose, much lower than the usual anesthetic dose, it can produce rapid relief from depression. This effect often occurs within 4 hours of IV administration. The effects persist for several weeks, but then without additional intervention, the depression often relapses. The drug has several significant side effects, including its general anesthetic effect as well as its psychotomimetic effect. Most experts consider it safe at lower doses; however, the clinical team should be ready to provide medical treatment should the drug have a profound effect on a patient's breathing or cause significant bradycardia.

Ketamine's enantiomer, esketamine (Ketanest), was approved by the FDA for the treatment of depression in adults in 2019. It has the advantage over ketamine, in that in addition to an injectable form, it is available as a nasal spray. Esketamine's mechanism of action is similar to ketamine's, although not identical; for example, both are noncompetitive NMDA receptor antagonist and inhibit dopamine transporters. However, esketamine does not act on the sigma receptors, which may account for part of ketamine's antidepressant effect. This lack of effect on sigma receptors is thought to reduce the psychotomimetic properties of the drug. It must be provided in a clinical setting that has the staff and facilities to observe the patient for at least 2 hours following administration. The main side effects are sedation, difficulties with vision and speaking, and cognitive effects, including confusion, dissociation, and potentially delirium. It may also cause anxiety and increased BP in some patients.

GABA$_A$ Allosteric Modulators

Brexanolone, also called allopregnanolone, was approved in the United States in 2019 under the priority review process as a breakthrough therapy for the treatment of postpartum depression. It is a neurosteroid which positively modulates the GABA$_A$ receptor. It is also a negative allosteric modulator of

the nicotinic acetylcholine receptor and may have action on serotonin HT_3 as well. The mechanism of its antidepressant effect is not clear, as other positive allosteric modulators of $GABA_A$, such as benzodiazepines, do not have a significant antidepressant effect. However, like ketamine, it provides a rapid response in patients who respond to the drug, usually within 2 to 3 days. We know little about the long term efficacy of the drug.

The drug is marketed under the brand name Zulresso and is a Schedule IV controlled substance. It is only available through a national registry and has several other drawbacks limiting its widespread acceptance. One is its long administration time, as the drug must be given by continuous IV infusion over 60 hours, during which the dose is slowly increased. This extended hospitalization is to prevent excess sedation or syncope.

Perhaps the most significant drawback of the medication is its cost. Currently, the drug costs about $34,000 for a single dose, as well as the price of remaining in a medical facility for 60 hours, and is not currently covered by most insurance companies.

▲ 21.3 Mood Stabilizers

LITHIUM

The effectiveness of lithium for mania and the prophylactic treatment of manic–depressive disorder was established in the early 1950s as a result of research done by John F.J. Cade, an Australian psychiatrist. Concerns about toxicity limited initial acceptance of lithium use in the United States, but its use increased gradually in the late 1960s. It was not until 1970 that the FDA approved its labeling for the treatment of mania. The only other approved FDA indication came in 1974 when it was accepted as maintenance therapy in patients with a history of mania. For several decades, lithium was the only drug approved for both acute and maintenance treatment. It is also used as an adjunctive medication in the treatment of MDD.

Lithium (Li), a monovalent ion, is a member of the group IA alkali metals on the periodic table, a group that also includes sodium, potassium, rubidium, cesium, and francium. Lithium exists in nature as both ^{6}Li (7.42 percent) and

^{7}Li (92.58 percent). The latter isotope allows the imaging of lithium by magnetic resonance spectroscopy. Some 300 mg of lithium is contained in 1,597 mg of lithium carbonate (Li_2CO_3). Most lithium used in the United States is obtained from dry lake mining in Chile and Argentina.

Pharmacologic Actions

Lithium is rapidly and completely absorbed after oral administration, with peak serum concentrations occurring in 1 to 1.5 hours with standard preparations and in 4 to 4.5 hours with slow-release and controlled-release preparations. Lithium does not bind to plasma proteins, is not metabolized, and is excreted through the kidneys. The plasma half-life is initially 1.3 days and is 2.4 days after administration for more than 1 year. The blood–brain barrier permits only the slow passage of lithium, which is why a single overdose does not necessarily cause toxicity and why long-term lithium intoxication is slow to resolve. The elimination half-life of lithium is 18 to 24 hours in young adults but is shorter in children and more prolonged in elderly persons. Renal clearance of lithium is decreased with renal insufficiency. Equilibrium is reached after 5 to 7 days of regular intake. Obesity is associated with higher rates of lithium clearance. The excretion of lithium is complex during pregnancy; excretion increases during pregnancy but decreases after delivery. Lithium is excreted in breast milk and insignificant amounts in the feces and sweat. Thyroid and renal concentrations of lithium are higher than serum levels.

An explanation for the mood-stabilizing effects of lithium remains elusive. Theories include alterations of ion transport and effects on neurotransmitters and neuropeptides, signal transduction pathways, and second messenger systems.

Therapeutic Indications

Bipolar I Disorder

MANIC EPISODES. Lithium controls acute mania and prevents relapse in about 80 percent of persons with bipolar I disorder and in a somewhat smaller percentage of persons with mixed (mania and depression) episodes, rapid-cycling bipolar disorder, or mood changes in encephalopathy. Lithium has a

relatively slow onset of action when used and exerts its antimanic effects over 1 to 3 weeks. Thus, a benzodiazepine, DRA, SDA, or valproic acid is usually administered for the first few weeks. Patients with mixed or dysphoric mania, rapid cycling, comorbid substance abuse, or organicity respond less well to lithium than those with classic mania.

BIPOLAR DEPRESSION. Lithium is effective in the treatment of depression associated with bipolar I disorder, as well as in the role of add-on therapy for patients with severe MDD. Augmentation of lithium therapy with valproic acid (Depakene) or carbamazepine (Tegretol) is usually well tolerated, with little risk of precipitation of mania.

When a depressive episode occurs in a person taking maintenance lithium, the differential diagnosis should include lithium-induced hypothyroidism, substance abuse, and lack of compliance with lithium therapy. One approach is to increase the lithium concentration (up to 1 to 1.2 mEq/L). Alternately we may augment with valproate or carbamazepine. It may also help to add supplemental thyroid hormone (e.g., 25 µg a day of liothyronine [Cytomel]), even in the presence of normal findings on thyroid function tests. Antidepressants or ECT are sometimes added judiciously. After the acute depressive episode resolves, other therapies should be tapered in favor of lithium monotherapy, if clinically tolerated.

MAINTENANCE. Maintenance treatment with lithium markedly decreases the frequency, severity, and duration of manic and depressive episodes in persons with bipolar I disorder. Lithium provides relatively more effective prophylaxis for mania than for depression, and supplemental antidepressant strategies may be necessary either intermittently or continuously. Lithium maintenance is almost always indicated after the first episode of bipolar I disorder, depression or mania, and should be considered after the first episode for adolescents or for persons who have a family history of bipolar I disorder. Others who benefit from lithium maintenance are those who have poor support systems, had no precipitating factors for the first episode, have a high suicide risk, had a sudden onset of the first episode, or had a first episode of mania. Clinical studies have shown that lithium reduces the incidence of suicide in bipolar I disorder patients six- or sevenfold. Lithium is also an effective treatment for persons with severe cyclothymic disorder.

It is wise to initiate maintenance therapy after the first manic episode, based on several observations. First, each episode of mania increases the risk of subsequent episodes. Second, among people responsive to lithium, relapses are 28 times more likely after lithium use is discontinued. Third, case reports describe persons who initially responded to lithium, discontinued taking it, and then had a relapse but no longer responded to lithium in subsequent episodes. Continued maintenance treatment with lithium is often associated with increased efficacy and reduced mortality. Therefore, an episode of depression or mania that occurs after a relatively short time on lithium maintenance does not necessarily represent treatment failure. However, lithium treatment alone may begin to lose its effectiveness after several years of successful use. If this occurs, then supplemental treatment with carbamazepine or valproate may be useful.

Maintenance lithium dosages can often be adjusted to achieve plasma concentration somewhat lower than that needed for the treatment of acute mania. If lithium use is to be discontinued, then the dosage should be slowly tapered. Abrupt discontinuation of lithium therapy is associated with an increased risk of recurrence of manic and depressive episodes.

Major Depressive Disorder. Lithium is effective in the long-term treatment of major depression, but it is not more effective than antidepressant drugs. The most common role for lithium in MDD is as an adjuvant to antidepressant use in persons who have failed to respond to the antidepressants alone. About 50 to 60 percent of antidepressant nonresponders do respond when lithium, 300 mg three times daily, is added to the antidepressant regimen. In some cases, a response may be seen within days, but most often, several weeks are required to see the efficacy of the regimen. Lithium alone may effectively treat depressed persons who have bipolar I disorder but have not yet had their first manic episode. Lithium has been reported to be effective in persons with MDD whose disorder has marked cyclicity.

Schizoaffective Disorder and Schizophrenia. Persons with prominent mood symptoms—either bipolar type or depressive type—with schizoaffective disorder are more likely to respond to lithium than those with predominant psychotic symptoms. Although SDAs and DRAs are the

treatments of choice for persons with schizoaffective disorder, lithium is a useful augmentation agent. This approach is particularly true for persons whose symptoms are resistant to treatment with SDAs and DRAs. Lithium augmentation of an SDA or DRA medication may be an effective treatment for persons with schizoaffective disorder even in the absence of a prominent mood disorder component. Some persons with schizophrenia who cannot take antipsychotic drugs may benefit from lithium treatment alone.

Other Indications. Over the years, reports have appeared about the use of lithium to treat a wide range of other psychiatric and nonpsychiatric conditions (Tables 21-25 and 21-26). The effectiveness and safety of lithium for most of these disorders have not been confirmed. Lithium has an anti-aggressive activity that is separate from its effects on mood. Aggressive outbursts in persons with schizophrenia, violent prison inmates, and children with conduct disorder and aggression, or self-mutilation in persons with intellectual disability, can sometimes be controlled with lithium.

Table 21-25
Psychiatric Uses of Lithium

Well established (FDA approved)
　　Bipolar disorder
　　　Manic episode
　　　Maintenance therapy

Reasonably well established
　　Bipolar I disorder, depressive episode
　　Bipolar II disorder
　　Rapid-cycling bipolar I disorder
　　Cyclothymic disorder
　　Major depressive disorder
　　　Acute depression (as an augmenting agent)
　　　Maintenance therapy
　　Schizoaffective disorder

Evidence of benefit in particular groups
　　Schizophrenia

Aggression (episodic), explosive behavior, and self-mutilation
Conduct disorder in children and adolescents
Intellectual disability
Cognitive disorders
Aggressive prisoners

Anecdotal, controversial, unresolved, or doubtful
Alcohol and other substance-related disorders
Cocaine abuse
Substance-induced mood disorder with manic features
Obsessive-compulsive disorder
Phobias
Posttraumatic stress disorder
ADHD
Eating disorders
  Anorexia nervosa
  Bulimia nervosa
Impulse-control disorders
Kleine–Levin syndrome
Mental disorders caused by a general medical condition (e.g., mood disorder caused by a general medical condition with manic features)
Periodic catatonia
Periodic hypersomnia
Personality disorders (e.g., antisocial, borderline, emotionally unstable, schizotypal)
Premenstrual dysphoric disorder
Sexual disorders
  Transvestism
  Exhibitionism
  Pathologic hypersexuality

FDA, Food and Drug Administration; ADHD, attention-deficit/hyperactivity disorder.

Nonpsychiatric Uses of Lithium*a*

Neurologic
  Epilepsy
  Headache (chronic cluster, hypnic, migraine, particularly cyclic)
  Ménière disease (not supported by controlled studies)
  Movement disorders
  Huntington disease
  L-Dopa–induced hyperkinesias
  On–off phenomenon in Parkinson disease (controlled study found decreased akinesia but development of dyskinesia in a few cases)
  Spasmodic torticollis
  Tardive dyskinesia (not supported by controlled studies, and pseudoparkinsonism has been reported)
  Tourette disorder
  Pain (facial pain syndrome, painful shoulder syndrome, fibromyalgia)
  Periodic paralysis (hypokalemic and hypermagnesic but not hyperkalemic)
Hematologic
  Aplastic anemia
  Cancer—chemotherapy-induced, radiotherapy-induced
  Neutropenia (one study found increased risk of sudden death in patients with preexisting cardiovascular disorder)
  Drug-induced neutropenia (e.g., from carbamazepine, antipsychotics, immunosuppressives, and zidovudine)
  Felty syndrome
  Leukemia
Endocrine
  Thyroid cancer as an adjunct to radioactive iodine
  Thyrotoxicosis
  Syndrome of inappropriate antidiuretic hormone secretion
Cardiovascular
  Antiarrhythmic agent (animal data only)
Dermatologic
  Genital herpes (controlled studies support topical and oral use)

Eczematoid dermatitis
Seborrheic dermatitis (controlled study supports)
Gastrointestinal
Cyclic vomiting
Gastric ulcers
Pancreatic cholera
Ulcerative colitis
Respiratory
Asthma (controlled study did not support)
Cystic fibrosis
Other
Bovine spastic paresis

aAll the uses listed here do not have Food and Drug Administration(FDA)–approved labeling. There are conflicting reports about many of these uses—some have negative findings in controlled studies, and a few involve reports of possible adverse effects.

L-Dopa, levodopa.

Precautions and Adverse Effects

More than 80 percent of patients taking lithium experience side effects. It is crucial to minimize the risk of adverse events through monitoring of lithium blood levels and to use appropriate pharmacologic interventions to counteract unwanted effects when they occur. The most common adverse effects are summarized in Table 21-27. Patient education can play an essential role in reducing the incidence and severity of side effects. Patients taking lithium should be advised that changes in the body's water and salt content can affect the amount of lithium excreted, resulting in either increases or decreases in lithium concentrations. Excessive sodium intake (e.g., a dramatic dietary change) lowers lithium concentrations.

Table 21-27
Adverse Effects of Lithium

Neurologic
Benign, nontoxic: dysphoria, lack of spontaneity, slowed reaction time, memory difficulties
Tremor: postural, occasional extrapyramidal

Toxic: coarse tremor, dysarthria, ataxia, neuromuscular irritability, seizures, coma, death

Miscellaneous: peripheral neuropathy, benign intracranial hypertension, myasthenia gravis–like syndrome, altered creativity, lowered seizure threshold

Endocrine

Thyroid: goiter, hypothyroidism, exophthalmos, hyperthyroidism (rare)

Parathyroid: hyperparathyroidism, adenoma

Cardiovascular

Benign T-wave changes, sinus node dysfunction

Renal

Concentrating defect, morphologic changes, polyuria (nephrogenic diabetes insipidus), reduced GFR, nephrotic syndrome, renal tubular acidosis

Dermatologic

Acne, hair loss, psoriasis, rash

Gastrointestinal

Appetite loss, nausea, vomiting, diarrhea

Miscellaneous

Altered carbohydrate metabolism, weight gain, fluid retention

GFR, glomerular filtration rate.

Conversely, too little sodium (e.g., fad diets) can lead to potentially toxic concentrations of lithium. Decreases in body fluid (e.g., excessive perspiration) can lead to dehydration and lithium intoxication. Patients should report whenever another clinician prescribes medications, because many commonly used agents can affect lithium concentrations.

Cardiac Effects. Lithium can cause diffuse slowing, widening of the frequency spectrum, and potentiation and disorganization of background rhythm on electrocardiography (ECG). Bradycardia and cardiac arrhythmias may occur, especially in people with cardiovascular disease. Lithium infrequently reveals Brugada syndrome, an inherited, life-threatening heart problem that some people may have without knowing it. It can cause a severe

abnormal heartbeat and other symptoms (such as severe dizziness, fainting, shortness of breath) that need medical attention right away. Before starting lithium treatment, clinicians should ask about known heart conditions, unexplained fainting, and family history of problems or sudden unexplained death before age 45.

Gastrointestinal Effects. GI symptoms—which include nausea, decreased appetite, vomiting, and diarrhea—can be diminished by dividing the dosage, administering the lithium with food, or switching to another lithium preparation. The lithium preparation least likely to cause diarrhea is lithium citrate. Some lithium preparations contain lactose, which can cause diarrhea in lactose-intolerant persons. Persons taking slow-release formulations of lithium who experience diarrhea caused by unabsorbed medication in the lower part of the GI tract may experience less diarrhea than with standard-release preparations. Diarrhea may also respond to antidiarrheal preparations such as loperamide (Imodium, Kaopectate), bismuth subsalicylate (Pepto-Bismol), or diphenoxylate with atropine (Lomotil).

Weight Gain. Weight gain results from a poorly understood effect of lithium on carbohydrate metabolism. Weight gain can also result from lithium-induced hypothyroidism, lithium-induced edema, or excessive consumption of soft drinks and juices to quench lithium-induced thirst.

Neurologic Effects

TREMOR. A lithium-induced postural tremor may occur that is usually 8 to 12 Hz and is most notable in outstretched hands, especially in the fingers, and during tasks involving fine manipulations. The tremor can be reduced by dividing the daily dosage, using a sustained-release formulation, reducing caffeine intake, reassessing the concomitant use of other medicines, and treating comorbid anxiety. β-Adrenergic receptor antagonists, such as propranolol, 30 to 120 mg a day in divided doses, and primidone (Mysoline), 50 to 250 mg a day, are usually effective in reducing the tremor. In persons with hypokalemia, potassium supplementation may improve the tremor. When a person taking lithium has a severe tremor, the possibility of lithium toxicity should be suspected and evaluated.

COGNITIVE EFFECTS. Lithium use has been associated with dysphoria, lack of spontaneity, slowed reaction times, and impaired memory. We should note these symptoms carefully because they are a frequent cause of noncompliance. The differential diagnosis for such symptoms should include depressive disorders, hypothyroidism, hypercalcemia, other illnesses, and other drugs. Some, but not all, persons have reported that fatigue and mild cognitive impairment decrease with time.

OTHER NEUROLOGIC EFFECTS. Uncommon neurologic adverse effects include symptoms of mild parkinsonism, ataxia, and dysarthria, although the last two symptoms may also be attributable to lithium intoxication. Lithium is rarely associated with the development of peripheral neuropathy, benign intracranial hypertension (pseudotumor cerebri), findings resembling myasthenia gravis, and increased risk of seizures.

Renal Effect.
The most common adverse renal effect of lithium is polyuria with secondary polydipsia. The symptom is particularly a problem in 25 to 35 percent of persons taking lithium who may have a urine output of more than 3 L a day (reference range: 1 to 2 L a day). The polyuria primarily results from lithium antagonism to the effects of antidiuretic hormone, which thus causes diuresis. When polyuria is a significant problem, the person's renal function should be evaluated and followed up with 24-hour urine collections for creatinine clearance determinations. Treatment consists of fluid replacement, the use of the lowest effective dosage of lithium, and single daily dosing of lithium. Treatment can also involve the use of a thiazide or potassium-sparing diuretic. For example, amiloride (Midamor), spironolactone (Aldactone), triamterene (Dyrenium), or amiloride–hydrochlorothiazide (Moduretic) may help. If treatment with a diuretic is initiated, the lithium dosage should be halved, and the diuretic should not be started for 5 days, because the diuretic is likely to increase lithium retention.

The most severe renal adverse effects, which are rare and associated with continuous lithium administration for 10 years or more, involve the appearance of nonspecific interstitial fibrosis, associated with gradual decreases in glomerular filtration rate and increases in serum creatinine concentrations, and rarely with renal failure. Lithium is occasionally

associated with nephrotic syndrome and features of distal renal tubular acidosis. Another pathologic finding in patients with lithium nephropathy is the presence of microcysts. Magnetic resonance imaging (MRI) can be used to demonstrate renal microcysts secondary to chronic lithium nephropathy and therefore avoid renal biopsy. It is prudent for persons taking lithium to check their serum creatinine concentration, urine chemistries, and 24-hour urine volume at 6-month intervals. If creatinine levels do rise, then more frequent monitoring and MRI might be considered.

Thyroid Effects. Lithium causes a generally benign and often transient diminution in the concentrations of circulating thyroid hormones. Reports have attributed goiter (5 percent of persons), benign reversible exophthalmos, hyperthyroidism, and hypothyroidism (7 to 10 percent of persons) to lithium treatment. Lithium-induced hypothyroidism is more common in women (14 percent) than in men (4.5 percent). Women are at the highest risk during the first 2 years of treatment. Persons taking lithium to treat bipolar disorder are twice as likely to develop hypothyroidism if they develop rapid cycling. About 50 percent of persons receiving long-term lithium treatment have laboratory abnormalities, such as an abnormal TRH response, and about 30 percent have elevated concentrations of TSH. If symptoms of hypothyroidism are present, replacement with levothyroxine (Synthroid) is indicated. Even in the absence of hypothyroid symptoms, some clinicians treat persons with significantly elevated TSH concentrations with levothyroxine. In lithium-treated persons, TSH concentrations should be measured every 6 to 12 months. Lithium-induced hypothyroidism should be considered when evaluating depressive episodes that emerge during lithium therapy.

Cardiac Effects. The cardiac effects of lithium resemble those of hypokalemia on ECG. The displacement of intracellular potassium by the lithium ion causes this. The most common changes on the ECG are T-wave flattening or inversion. The changes are benign and disappear after lithium is excreted from the body.

Lithium depresses the pacemaking activity of the sinus node, sometimes resulting in sinus dysrhythmias, heart block, and episodes of syncope. Lithium treatment, therefore, is contraindicated in persons with sick sinus syndrome. In rare cases, ventricular arrhythmias and congestive heart failure

have been associated with lithium therapy. Lithium cardiotoxicity is prevalent in persons on a low-salt diet, those taking certain diuretics or ACEIs, and those with fluid–electrolyte imbalances or any renal insufficiency.

Dermatologic Effects. Dermatologic effects may be dose-dependent. They include acneiform, follicular, and maculopapular eruptions; pretibial ulcerations; and worsening of psoriasis. Occasionally, aggravated psoriasis or acneiform eruptions may force the discontinuation of lithium treatment. Alopecia has also been reported. Persons with many of those conditions respond favorably to changing to another lithium preparation and the usual dermatologic measures. Lithium concentrations should be monitored if tetracycline is used for the treatment of acne because it can increase the retention of lithium.

Lithium Toxicity and Overdoses. The early signs and symptoms of lithium toxicity include neurologic symptoms, such as coarse tremor, dysarthria, and ataxia; GI symptoms; cardiovascular changes; and renal dysfunction. The later signs and symptoms include impaired consciousness, muscular fasciculations, myoclonus, seizures, and coma. Signs and symptoms of lithium toxicity are outlined in Table 21-28. Risk factors include exceeding the recommended dosage, renal impairment, low-sodium diet, drug interaction, and dehydration. Elderly persons are more vulnerable to the effects of increased serum lithium concentrations. The greater the degree and duration of elevated lithium concentrations, the worse are the symptoms of lithium toxicity.

Table 21-28
Signs and Symptoms of Lithium Toxicity

1. Mild to moderate intoxication (lithium level, 1.5–2.0 mEq/L)	
GI	Vomiting
	Abdominal pain
	Dryness of mouth
Neurologic	Ataxia
	Dizziness

Slurred speech
Nystagmus
Lethargy or excitement
Muscle weakness

2. Moderate to severe intoxication (lithium level: 2.0–2.5 mEq/L)

GI	Anorexia
	Persistent nausea and vomiting
Neurologic	Blurred vision
	Muscle fasciculations
	Clonic limb movements
	Hyperactive deep tendon reflexes
	Choreoathetoid movements
	Convulsions
	Delirium
	Syncope
	Electroencephalographic changes
	Stupor
	Coma
	Circulatory failure (lowered BP, cardiac arrhythmias, and conduction abnormalities)

3. Severe lithium intoxication (lithium level >2.5 mEq/L)

Generalized convulsions
Oliguria and renal failure
Death

Lithium toxicity is a medical emergency, potentially causing permanent neuronal damage and death. In cases of toxicity (Table 21-29), lithium should be stopped and dehydration treated. Unabsorbed lithium can be removed from the GI tract by ingestion of sodium polystyrene sulfonate (Kayexalate) or polyethylene glycol solution (GoLYTELY), but not activated charcoal. Ingestion of a single large dose may create clumps of medication in the stomach, which can be removed by gastric lavage with a wide-bore tube. The

value of forced diuresis is still debated. In severe cases, hemodialysis rapidly removes excessive amounts of serum lithium. Postdialysis serum lithium concentrations may increase as lithium is redistributed from tissues to the blood, so repeat dialysis may be needed. Neurologic improvement may lag behind the clearance of serum lithium by several days because lithium crosses the blood–brain barrier slowly.

Table 21-29
Management of Lithium Toxicity

1. Contact personal physician or go to a hospital emergency department
2. Lithium should be discontinued
3. Vital signs and a neurologic examination with complete formal mental status examination
4. Lithium level, serum electrolytes, renal function tests, and ECG
5. Emesis, gastric lavage, and absorption with Kayexalate or GoLYTELY
6. For any patient with a serum lithium level greater than 4.0 mEq/L, hemodialysis

ECG, electrocardiography.

Adolescents. The serum lithium concentrations for adolescents are similar to those for adults. Weight gain and acne associated with lithium use can be particularly troublesome to adolescents.

Elderly Persons. Lithium is a safe and effective drug for elderly persons. However, the treatment of elderly persons taking lithium may be complicated by the presence of other medical illnesses, decreased renal function, special diets that affect lithium clearance, and generally increased sensitivity to lithium. Elderly persons should initially be given low dosages, their dosages should be switched less frequently than those of younger persons, and a longer time must be allowed for renal excretion to equilibrate with absorption before lithium can be assumed to have reached its steady-state concentrations.

Pregnant Women. Lithium should not be administered to pregnant women in the first trimester because of the risk of congenital disabilities. The most common malformations involve the cardiovascular system, most commonly Ebstein anomaly of the tricuspid valves. The risk of Ebstein malformation in lithium-exposed fetuses is 1 in 1,000, which is 20 times the risk in the general population. The possibility of fetal cardiac anomalies can be evaluated with fetal echocardiography. The teratogenic risk of lithium (4 to 12 percent) is higher than that for the general population (2 to 3 percent) but appears to be lower than that associated with the use of valproate or carbamazepine. A woman who continues to take lithium during pregnancy should use the lowest effective dosage. The maternal lithium concentration must be monitored closely during pregnancy, and especially after pregnancy, because of the significant decrease in renal lithium excretion as the renal function returns to normal in the first few days after delivery. Adequate hydration can reduce the risk of lithium toxicity during labor. Lithium prophylaxis is recommended for all women with bipolar disorder as they enter the postpartum period. Lithium is excreted into breast milk and should be taken by a nursing mother only after careful evaluation of potential risks and benefits. Signs of lithium toxicity in infants include lethargy, cyanosis, abnormal reflexes, and sometimes hepatomegaly.

Miscellaneous Effects. Lithium should be used with caution in diabetic persons, who should monitor their blood glucose concentrations carefully to avoid diabetic ketoacidosis. Benign, reversible leukocytosis is commonly associated with lithium treatment. Dehydrated, debilitated, and medically ill persons are most susceptible to adverse effects and toxicity.

Drug Interactions

Lithium drug interactions are summarized in Table 21-30.

Lithium is commonly used in conjunction with DRAs. This combination is typically sufficient and safe. However, coadministration of higher dosages of a DRA and lithium may result in a synergistic increase in the symptoms of lithium-induced neurologic side effects and neuroleptic extrapyramidal symptoms. In rare instances, encephalopathy has been reported with this combination.

The coadministration of lithium and carbamazepine, lamotrigine, valproate, and clonazepam may increase lithium concentrations and aggravate lithium-induced neurologic adverse effects. Treatment with the combination should be initiated at slightly lower dosages than usual, and the dosages should be increased gradually. Changes from one to another treatment for mania should be made carefully, with as little temporal overlap between the drugs as possible.

Most diuretics (e.g., thiazide and potassium-sparing) can increase lithium concentrations; when treatment with such a diuretic is stopped, the clinician may need to increase the person's daily lithium dosage. Osmotic and loop diuretics, carbonic anhydrase inhibitors, and xanthines (including caffeine) may reduce lithium concentrations to below therapeutic concentrations. Whereas ACEIs may cause an increase in lithium concentrations, the AT_1 angiotensin II receptor inhibitors losartan (Cozaar) and irbesartan (Avapro) do not alter lithium concentrations. A wide range of NSAIDs can decrease lithium clearance, thereby increasing lithium concentrations. These drugs include indomethacin (Indocin), phenylbutazone (Azolid), diclofenac (Voltaren), ketoprofen (Orudis), oxyphenbutazone (Oxalid), ibuprofen (Motrin, Advil), piroxicam (Feldene), and naproxen (Naprosyn). Aspirin and sulindac (Clinoril) do not affect lithium concentrations.

The coadministration of lithium and quetiapine (Seroquel) may cause somnolence but is otherwise well tolerated. The coadministration of lithium and ziprasidone (Geodon) may modestly increase the incidence of tremors. The coadministration of lithium and calcium channel inhibitors should be avoided because of potentially fatal neurotoxicity.

A person taking lithium who is about to undergo ECT should discontinue taking lithium 2 days before beginning ECT to reduce the risk of delirium.

Laboratory Interferences

Lithium does not interfere with any laboratory tests, but lithium-induced alterations include an increased WBC count, decreased serum thyroxine, and increased serum calcium. Blood collected in a lithium–heparin anticoagulant tube will produce falsely elevated lithium concentrations.

Dosage and Clinical Guidelines

Initial Medical Workup. All patients should have a routine laboratory workup and physical examination before being started on lithium. The laboratory tests should include serum creatinine concentration (or a 24-hour urine creatinine if the clinician has any reason to be concerned about renal function), electrolytes, thyroid function (TSH, T_3 [triiodothyronine], and T_4 [thyroxine]), a CBC, ECG, and a pregnancy test in women of childbearing age.

Dosage Recommendations. Lithium formulations include immediate-release 150-, 300-, and 600-mg lithium carbonate capsules (Eskalith and generic), 300 mg lithium carbonate tablets (Lithotabs), 450-mg controlled-release lithium carbonate capsules (Eskalith CR and Lithonate), and 8 mEq/5 mL of lithium citrate syrup.

The starting dosage for most adults is 300 mg of the regular-release formulation three times daily. The starting dosage for elderly persons or persons with renal impairment should be 300 mg once or twice daily. After stabilization, dosages between 900 and 1,200 mg a day usually produce a therapeutic plasma concentration of 0.6 to 1 mEq/L, and a daily dose of 1,200 to 1,800 mg usually produces a therapeutic concentration of 0.8 to 1.2 mEq/L. Maintenance dosing can be given either in two or three divided doses of the regular-release formulation or in a single dosage of the sustained-release formulation equivalent to the combined daily dosage of the regular-release formulation. The use of divided doses reduces gastric upset and avoids single high-peak lithium concentrations. Discontinuation of lithium should be gradual to minimize the risk of early recurrence of mania and to permit recognition of early signs of recurrence.

**Table 21-30
Drug Interactions with Lithium**

Drug Class	Reaction
Antipsychotics	Case reports of encephalopathy, worsening of extrapyramidal adverse effects, and neuroleptic malignant syndrome; inconsistent reports of altered red blood cell and plasma

	concentrations of lithium, antipsychotic drug, or both
Antidepressants	Occasional reports of a serotonin-like syndrome with potent serotonin reuptake inhibitors
Anticonvulsants	No significant pharmacokinetic interactions with carbamazepine or valproate; reports of neurotoxicity with carbamazepine; combinations helpful for treatment resistance
NSAIDs	May reduce renal lithium clearance and increase serum concentration; toxicity reported (exception is aspirin)
Diuretics	
Thiazides	Well-documented reduced renal lithium clearance and increased serum concentration; toxicity reported
Potassium sparing	Limited data; may increase lithium concentration
Loop	Lithium clearance unchanged (some case reports of increased lithium concentration)
Osmotic (mannitol, urea)	Increase renal lithium clearance and decrease lithium concentration
Xanthine (aminophylline, caffeine, theophylline)	Increase renal lithium clearance and decrease lithium concentration
Carbonic anhydrase inhibitors (acetazolamide)	Increase renal lithium clearance
ACEIs	Reports of reduced lithium clearance, increased

	concentrations, and toxicity
Calcium channel inhibitors	Case reports of neurotoxicity; no consistent pharmacokinetic interactions
Miscellaneous	
Succinylcholine, pancuronium	Reports of prolonged neuromuscular blockade
Metronidazole	Increased lithium concentration
Methyldopa	Few reports of neurotoxicity
Sodium bicarbonate	Increased renal lithium clearance
Iodides	Additive antithyroid effects
Propranolol	Used for lithium tremor; possible slight increase in lithium concentration

NSAID, nonsteroidal anti-inflammatory drug; ACEI, angiotensin-converting enzyme inhibitor.

Laboratory Monitoring. The periodic measurement of serum lithium concentration is an essential aspect of patient care, but it should always be combined with sound clinical judgment. A laboratory report listing the therapeutic range as 0.5 to 1.2 mEq/L may lull a clinician into disregarding early signs of lithium intoxication in patients whose levels are around 1.2 mEq/L. Clinical toxicity, especially in elderly persons, has been well documented at or slightly above the upper limit of the therapeutic range.

Regular monitoring of serum lithium concentrations is essential. Lithium levels should be obtained every 2 to 6 months except when there are signs of toxicity, during dosage adjustments, and in persons suspected to be noncompliant with the prescribed dosages. Under these circumstances, levels may be done weekly. Baseline ECG studies are essential and should be repeated annually.

When obtaining blood for lithium levels, patients should be at steady-state lithium dosing (usually after 5 days of constant dosing), preferably using a twice-daily or thrice-daily dosing regimen, and the blood sample must be drawn 12 hours (±30 minutes) after a given dose. Lithium concentrations 12

hours postdose in persons treated with sustained-release preparations are generally about 30 percent higher than the corresponding concentrations obtained from those taking the regular-release preparations. Because available data are based on a sample population following a multiple-dosage regimen, regular-release formulations given at least twice daily should be used for the initial determination of the appropriate dosages. Factors that may cause fluctuations in lithium measurements include dietary sodium intake, mood state, activity level, body position, and use of an improper blood sample tube.

Laboratory values that do not seem to correspond to clinical status may result from the collection of blood in a tube with a lithium–heparin anticoagulant (which can give results falsely elevated by as much as 1 mEq/L) or aging of the lithium ion-selective electrode (which can cause inaccuracies of up to 0.5 mEq/L). After the daily dose has been set, it is reasonable to change to the sustained-release formulation given once daily.

Effective serum concentrations for mania are 1.0 to 1.2 mEq/L, a level associated with 1,800 mg a day. The recommended range for maintenance treatment is 0.4 to 0.8 mEq/L, which is usually achieved with a daily dose of 900 to 1,200 mg. A small number of persons will not achieve therapeutic benefit with a lithium concentration of 1.2 mEq/L, yet will have no signs of toxicity. For such persons, titration of the lithium dosage to achieve a concentration above 1.2 mEq/L may be warranted. Some patients can be maintained at concentrations below 0.4 mEq/L. There may be considerable variation from patient to patient, so it is best to follow the maxim, "treat the patient, not the laboratory results." The only way to establish an optimal dose for a patient may be through trial and error.

Package inserts (US) for lithium products list effective serum concentrations for mania between 1.0 and 1.2 mEq/L (usually achieved with 1,800 mg of lithium carbonate daily) and for long-term maintenance between 0.6 and 1.2 mEq/L (usually achieved with 900 to 1,200 mg of lithium carbonate daily). The dose–blood level relationship may vary considerably from patient to patient. The likelihood of achieving a response at levels above 1.2 mEq/L is usually significantly outweighed by the increased risk of toxicity, although rarely a patient may both require and tolerate a higher-than-usual blood concentration.

What constitutes the lower end of the therapeutic range remains a matter of

debate. A prospective 3-year study found patients who maintained a concentration between 0.4 and 0.6 mEq/L (mean 0.54) were 2.6 times more likely to relapse than those who maintained between 0.8 and 1.0 mEq/L (mean 0.83). However, higher blood concentrations produced more adverse effects and were less well tolerated.

If there is no response after 2 weeks at a concentration that is beginning to cause adverse effects, then the person should taper off lithium over 1 to 2 weeks, and other mood-stabilizing drugs should be tried.

Patient Education. Lithium has a narrow therapeutic index, and many factors can upset the balance between lithium concentrations that are well tolerated and therapeutic, and those that produce side effects or toxicity. It is thus imperative that persons taking lithium be educated about signs and symptoms of toxicity, factors that affect lithium levels, how and when to obtain laboratory testing, and the importance of regular communication with the prescribing physician. Lithium concentrations can be disrupted by common factors such as excessive sweating from ambient heat or exercise or the use of widely prescribed agents such as ACEIs or NSAIDs. Patients may stop taking their lithium because they are feeling well or because they are experiencing side effects. They should be advised against discontinuing or modifying their lithium regimen. Table 21-31 lists some essential instructions for patients.

VALPROATE

Valproate (Depakene, Depakote), or valproic acid, is approved for the treatment of manic episodes associated with bipolar I disorder and is one of the most widely prescribed mood stabilizers in psychiatry. It has a rapid onset of action and is well-tolerated, and numerous studies suggest that it reduces the frequency and intensity of recurrent manic episodes over extended periods.

Chemistry

Valproate is a simple-chain branch carboxylic acid. It is called valproic acid because it is rapidly converted to the acid form in the stomach. Multiple formulations of valproic acid are marketed. These include valproic acid

(Depakene), divalproex sodium (Depakote), an enteric-coated delayed-release 1:1 mixture of valproic acid and sodium valproate available in tablet and sprinkle formulation (can be opened and spread on food); and sodium valproate injection (Depacon). Extended-release preparation is also available. Each of these is therapeutically equivalent because, at physiologic pH, valproic acid dissociates into valproate ion.

Table 21-31
Instructions to Patients Taking Lithium

Lithium can be remarkably effective in treating your disorder. If not used appropriately and not monitored closely, it can be ineffective and potentially harmful. It is important to keep the following instructions in mind.

Dosing

Take lithium exactly as directed by your doctor—never take more or less than the prescribed dose.

Do not stop taking without speaking to your doctor.

If you miss a dose, take it as soon as possible. If it is within 4 hr of the next dose, skip the missed dose (about 6 hr in the case of extended-release or slow-release preparations). Never double up doses.

Blood Tests

Comply with the schedule of recommended regular blood tests.

Despite their inconvenience and discomfort, your lithium blood levels, thyroid function, and kidney status need to be monitored as long as you take lithium.

When going to have lithium levels checked, you should have taken your last lithium dose 12 hr earlier.

Use of Other Medications

Do not start any prescription or over-the-counter medications without telling your doctor.

Even drugs such as ibuprofen (Advil, Motrin) and naproxen (Aleve) can significantly increase lithium levels.

Diet and Fluid Intake

Avoid sudden changes in your diet or fluid intake. If you do go on a diet, your doctor may need to increase the frequency of blood tests.

Caffeine and alcohol act as diuretics and can lower your lithium concentrations.

During treatment with lithium, it is recommended that you drink about 2 or 3 quarts of fluid daily and use normal amounts of salt.

Inform your doctor if you start or stop a low-salt diet.

Recognizing Potential Problems

If you engage in vigorous exercise or have an illness that causes sweating, vomiting, or diarrhea, consult your doctor because these might affect lithium levels.

Nausea, constipation, shakiness, increased thirst, frequency of urination, weight gain, or swelling of the extremities should be reported to your doctor.

Blurred vision, confusion, loss of appetite, diarrhea, vomiting, muscle weakness, lethargy, shakiness, slurred speech, dizziness, loss of balance, inability to urinate, or seizures could indicate severe toxicity and should prompt immediate medical attention.

Pharmacologic Actions

Regardless of how it is formulated, valproate is rapidly and completely absorbed 1 to 2 hours after oral administration, with peak concentrations occurring 4 to 5 hours after oral administration. The plasma half-life of valproate is 10 to 16 hours. Valproate is highly protein-bound. Protein binding becomes saturated at higher dosages, and concentrations of therapeutically effective free valproate increase at serum concentrations above 50 to 100 µg/mL. The unbound portion of valproate is considered to be pharmacologically active and can cross the blood–brain barrier. The extended-release preparation produces lower peak concentrations and higher minimum concentrations and can be given once a day. Valproate is metabolized primarily by hepatic glucuronidation and mitochondrial β

oxidation.

The biochemical basis of valproate's therapeutic effects remains poorly understood. Postulated mechanisms include enhancement of GABA activity, modulation of voltage-sensitive sodium channels, and action on extrahypothalamic neuropeptides.

Therapeutic Indications

Valproate is currently approved as monotherapy or adjunctive therapy of complex partial seizures, monotherapy and adjunctive therapy of simple and complex absence seizures, and adjunctive therapy for patients with multiple seizures that include absence seizures. Divalproex has additional indications for prophylaxis of migraine.

Bipolar I Disorder

ACUTE MANIA. About two-thirds of persons with acute mania respond to valproate. The majority of patients with mania usually respond within 1 to 4 days after achieving valproate serum concentrations above 50 µg/mL. The antimanic response is generally associated with levels greater than 50 µg/mL, in a range of 50 to 125 µg/mL. This serum concentration may be gradually achieved within 1 week of initiation of dosing, but rapid oral loading strategies achieve therapeutic serum concentrations in 1 day and can control manic symptoms within 5 days. The short-term antimanic effects of valproate can be augmented with the addition of lithium, carbamazepine (Tegretol), SDAs, or DRAs. Numerous studies have suggested that the irritable manic subtype responds significantly better to sodium valproate than lithium or placebo. Because of its more favorable profile of cognitive, dermatologic, thyroid, and renal adverse effects, valproate is preferred to lithium for the treatment of acute mania in children and elderly persons.

ACUTE BIPOLAR DEPRESSION. Valproate possesses some activity as a short-term treatment of depressive episodes in bipolar I disorder, but this effect is far less pronounced than for the treatment of manic episodes. Among depressive symptoms, valproate is more useful for the treatment of agitation than dysphoria. In clinical practice, valproate is most often used as add-on therapy to an antidepressant to prevent the development of mania or rapid

cycling.

PROPHYLAXIS. Studies suggest that valproate is useful in the prophylactic treatment of bipolar I disorder, resulting in fewer, less severe, and shorter manic episodes. In direct comparison, valproate is at least as effective as lithium and is better tolerated than lithium. It may be particularly useful in persons with rapid-cycling and ultrarapid-cycling bipolar disorders, dysphoric or mixed mania, and mania caused by a general medical condition as well as in persons who have comorbid substance use disorders or panic attacks and in persons who have not had complete favorable responses to lithium treatment.

Schizophrenia and Schizoaffective Disorder.

Valproate may accelerate response to antipsychotic therapy in patients with schizophrenia or schizoaffective disorder. Valproate alone is generally less effective in schizoaffective disorder than in bipolar I disorder. Valproate alone is ineffective for the treatment of psychotic symptoms and is typically used in combination with other drugs in patients with these symptoms.

Other Mental Disorders.

Valproate has been studied for possible efficacy in a broad range of psychiatric disorders. These include alcohol withdrawal and relapse prevention, panic disorder, PTSD, impulse control disorder, borderline personality disorder, and behavioral agitation and dementia. Evidence supporting use in these cases is weak, and any observed therapeutic effects may be related to the treatment of a comorbid bipolar disorder.

Precautions and Adverse Reactions

Although valproate treatment is generally well tolerated and safe, it carries quite a few black box warnings and other warnings (Table 21-32). The two most serious adverse effects of valproate treatment affect the pancreas and liver. Risk factors for potentially fatal hepatotoxicity include young age (younger than 3 years); concurrent use of phenobarbital; and the presence of neurologic disorders, especially inborn errors of metabolism. The rate of fatal hepatotoxicity in persons who have been treated with valproate alone is 0.85 per 100,000 persons; no persons older than the age of 10 years have been reported to have died from hepatotoxicity. Therefore, the risk of this adverse

reaction in adult psychiatric patients is low.

Table 21-32
Black Box Warnings and Other Warnings for Valproate

More Serious Side Effect	Management Considerations
Hepatotoxicity	Rare, idiosyncratic event Estimated risk, 1:118,000 (adults) Greatest risk profile (polypharmacy, younger than 2 yr of age, intellectual disability): 1:800
Pancreatitis	Rare, similar pattern to hepatotoxicity Incidence in clinical trial data is 2 in 2,416 (0.0008%) Postmarketing surveillance shows no increased incidence Relapse with rechallenge Asymptomatic amylase not predictive
Hyperammonemia	Rare; more common in combination with carbamazepine (Tegretol) Associated with coarse tremor and may respond to L-carnitine administration
Associated with urea cycle disorders	Discontinue valproate and protein intake Assess underlying urea cycle disorder Divalproex is contraindicated in patients with urea cycle disorders
Teratogenicity	Neural tube defect: 1–4% with valproate Preconceptual education and folate–vitamin B complex supplementation for all young women of childbearing potential
Somnolence in elderly persons	Slower titration than conventional doses Regular monitoring of fluid and nutritional intake

Thrombocytopenia	Decrease dose if clinically symptomatic (i.e., bruising, bleeding gums) Thrombocytopenia more likely with valproate levels ≥110 µg/mL (women) and ≥135 µg/mL (men)

Nevertheless, if symptoms of lethargy, malaise, anorexia, nausea and vomiting, edema, and abdominal pain occur in a person treated with valproate, the clinician must consider the possibility of severe hepatotoxicity. A modest increase in liver function test results does not correlate with the development of severe hepatotoxicity. Rare cases of pancreatitis have been reported; they occur most often in the first 6 months of treatment, and the condition occasionally results in death. The pancreatic function can be assessed and followed by serum amylase concentrations. Other potentially severe consequences of treatment include hyperammonemia-induced encephalopathy and thrombocytopenia. Thrombocytopenia and platelet dysfunction occur most commonly at high dosages and result in the prolongation of bleeding times.

There are multiple concerns regarding the use of valproate during pregnancy. Women who require valproate therapy should, therefore, inform their physicians if they intend to become pregnant. First-trimester use of valproate has been associated with a 3 to 5 percent risk of neural tube defects, as well as an increased risk of other malformations affecting the heart and other organ systems. Multiple reports have also indicated that in utero exposure to valproate may negatively affect cognitive development in children of mothers who take valproate during pregnancy. They have lower IQ scores at age 6 years compared with those exposed to other antiepileptic drugs. Fetal valproate exposure has dose-dependent associations with reduced cognitive abilities across a range of domains at 6 years of age. Valproate exposure may also increase the risk of autistic spectrum disorder.

Valproate is also associated with teratogenicity, most notably neural tube defects (e.g., spina bifida). The risk is about 1 to 4 percent of all women who take valproate during the first trimester of pregnancy. The risk of valproate-induced neural tube defects can be reduced with daily folic acid supplements (1 to 4 mg a day). All women with childbearing potential who take the drug

should be given folic acid supplements. Infants breastfed by mothers taking valproate develop serum valproate concentrations 1 to 10 percent of maternal serum concentrations, but no data suggest that this poses a risk to the infant. Valproate is not contraindicated in nursing mothers. We should avoid this drug in patients with hepatic diseases. Valproate may be especially problematic for adolescents and young women. Cases of polycystic ovarian disease have been reported in women using valproate. Even when the full syndromal criteria for this syndrome are not met, many of these women develop menstrual irregularities, hair loss, and hirsutism. These effects are thought to result from a metabolic syndrome that is driven by insulin resistance and hyperinsulinemia.

The common adverse effects associated with valproate (Table 21-33) are those affecting the GI system, such as nausea, vomiting, dyspepsia, and diarrhea. The GI effects are generally most common in the first month of treatment, significantly if the dosage is increased rapidly. Unbuffered valproic acid (Depakene) is more likely to cause GI symptoms than the enteric-coated "sprinkle" or the delayed-release divalproex sodium formulations. Other common adverse effects involve the nervous system, such as sedation, ataxia, dysarthria, and tremor. Valproate-induced tremor may respond well to treatment with β-adrenergic receptor antagonists or gabapentin. Treatment of the other neurologic adverse effects usually requires lowering the valproate dosage.

Weight gain is a common adverse effect, especially in long-term treatment, and can best be treated by strict limitation of caloric intake. Hair loss may occur in 5 to 10 percent of all persons treated, and rare cases of complete loss of body hair have been reported. Some clinicians have recommended treatment of valproate-associated hair loss with vitamin supplements that contain zinc and selenium. About 5 to 40 percent of persons experience a persistent but clinically insignificant elevation in liver transaminases up to three times the upper limit of normal, which is usually asymptomatic and resolves after discontinuation of the drug. High dosages of valproate (above 1,000 mg a day) may rarely produce mild to moderate hyponatremia, most likely because of some degree of the syndrome of secretion of inappropriate antidiuretic hormone, which is reversible upon lowering of the dosage. Overdoses of valproate can lead to coma and death.

Table 21-33
Adverse Effects of Valproate

Common
  GI irritation
  Nausea
  Sedation
  Tremor
  Weight gain
  Hair loss

Uncommon
  Vomiting
  Diarrhea
  Ataxia
  Dysarthria
  Persistent elevation of hepatic transaminases

Rare
  Fatal hepatotoxicity (primarily in pediatric patients)
  Reversible thrombocytopenia
  Platelet dysfunction
  Coagulation disturbances
  Edema
  Hemorrhagic pancreatitis
  Agranulocytosis
  Encephalopathy and coma
  Respiratory muscle weakness and respiratory failure

GI, gastrointestinal.

Drug Interactions

Valproate is commonly prescribed as part of a regimen involving other psychotropic agents. The only consistent drug interaction with lithium, if both drugs are maintained in their respective therapeutic ranges, is the exacerbation of drug-induced tremors, which can usually be treated with β-receptor antagonists. The combination of valproate and DRAs may result in increased sedation, as can be seen when valproate is added to any CNS

depressant (e.g., alcohol), and increased severity of extrapyramidal symptoms, which usually responds to treatment with antiparkinsonian drugs. Valproate can usually be safely combined with carbamazepine or SDAs. Perhaps the most worrisome interaction of valproate and a psychotropic drug involves lamotrigine. Since the approval of lamotrigine for the treatment of bipolar disorder, it is more likely that patients will be treated with both agents. Valproate more than doubles lamotrigine concentrations, increasing the risk of a severe rash (Stevens–Johnson syndrome and toxic epidermal necrolysis).

The plasma concentrations of carbamazepine, diazepam (Valium), amitriptyline (Elavil), nortriptyline (Pamelor), and phenobarbital (Luminal) may also be increased when these drugs are coadministered with valproate. Also, the plasma concentrations of phenytoin (Dilantin) and desipramine (Norpramin) may be decreased when they are combined with valproate. The plasma concentrations of valproate may be decreased when the drug is coadministered with carbamazepine and may be increased when coadministered with guanfacine (Tenex), amitriptyline, or fluoxetine (Prozac). Valproate can be displaced from plasma proteins by carbamazepine, diazepam, and aspirin. Persons who are treated with anticoagulants (e.g., aspirin and warfarin [Coumadin]) should also be monitored when valproate use is initiated to assess the development of any undesired augmentation of the anticoagulation effects. Interactions of valproate with other drugs are listed in Table 21-34.

Table 21-34
Interactions of Valproate with Other Drugs

Drug	Interactions Reported with Valproate
Lithium	Increased tremor
Antipsychotics	Increased sedation; increased extrapyramidal effects; delirium and stupor (single report)
Clozapine	Increased sedation; confusional syndrome (single report)
Carbamazepine	Acute psychosis (single report); ataxia, nausea,

	lethargy (single report); may decrease valproate serum concentrations
Antidepressants	Amitriptyline and fluoxetine may increase valproate serum concentrations
Diazepam	Serum concentration increased by valproate
Clonazepam	Absence status (rare; reported only in patients with preexisting epilepsy)
Phenytoin	Serum concentration decreased by valproate
Phenobarbital	Serum concentration increased by valproate; increased sedation
Other CNS depressants	Increased sedation
Anticoagulants	Possible potentiation of effect

CNS, central nervous system.

Laboratory Interferences

Valproate may cause a laboratory increase of serum-free fatty acids. Valproate metabolites may produce a false-positive test result for urinary ketones as well as falsely abnormal thyroid function test results.

Table 21-35
Recommended Laboratory Tests during Valproate Therapy

Before Treatment
    Standard chemistry screen with special attention to liver function tests
    CBC, including WBC and platelet count
During Treatment
    Liver function tests at 1 mo; then every 6–24 mo if no abnormalities are found.
    Complete blood count with platelet count at 1 mo; then every 6–24 mo if findings are normal.

If Liver Function Test Results Become Abnormal
Mild transaminase elevation (less than three times normal): monitoring every 1–2 wk; if stable and patient is responding to valproate, results are monitored monthly to every 3 mo.
Pronounced transaminase elevation (more than three times normal): dosage reduction or discontinuation of valproate; increase dose or rechallenge if transaminases normalize and if the patient is a valproate responder.

CBC, complete blood count; WBC, white blood cell.

Dosage and Clinical Guidelines

When starting valproate therapy, a baseline hepatic panel, CBC and platelet counts, and pregnancy testing should be ordered. Additional testing should include amylase and coagulation studies if baseline pancreatic disease or coagulopathy is suspected. In addition to baseline laboratory tests, hepatic transaminase concentrations should be obtained 1 month after initiation of therapy and every 6 to 24 months after that. However, because even frequent monitoring may not predict severe organ toxicity, it is more prudent to reinforce the need for prompt evaluation of any illnesses when reviewing the instructions with patients. Asymptomatic elevation of transaminase concentrations up to three times the upper limit of normal are typical and do not require any change in dosage. Table 21-35 lists the recommended laboratory tests for valproate treatment.

Valproate is available in several formulations (Table 21-36). For the treatment of acute mania, an oral loading strategy of initiation with 20 to 30 mg/kg a day can be used to accelerate the control of symptoms. This strategy is usually well tolerated but can cause excessive sedation and tremor in elderly persons. Agitated behavior can be rapidly stabilized with IV infusion of valproate. If acute mania is absent, it is best to initiate drug treatment gradually to minimize the common adverse effects of nausea, vomiting, and sedation. The dose on the first day should be 250 mg administered with a meal. The dosage can be raised to 250 mg orally three times daily for over 3 to 6 days. The plasma concentrations can be assessed in the morning before the first daily dose is administered. Therapeutic plasma concentrations for the control of seizures range between 50 and 100 µg/mL. It is reasonable to use

the same range for the treatment of mental disorders; most of the controlled studies have used 50 to 125 µg/mL. Most persons attain therapeutic plasma concentrations on a dosage between 1,200 and 1,500 mg a day in divided doses. After a person's symptoms are well controlled, the full daily dose can be taken all at once before sleep.

Table 21-36
Valproate Preparations Available in the United States

Generic Name	Trade Name, Form (Doses)	Time to Peak
Valproate sodium injection	Depacon injection (100-mg valproic acid/mL)	1 hr
Valproic acid	Depakene, syrup (250 mg/5 mL)	1–2 hr
	Depakene, capsules (250 mg)	1–2 hr
Divalproex sodium	Depakote, delayed-released tablets (125, 250, 500 mg)	3–8 hr
Divalproex sodium-coated particles in	Depakote, sprinkle capsules (125 mg)	Compared with divalproex tablets, divalproex sprinkle has earlier onset and slower absorption, with slightly lower peak plasma concentration

capsules		
Divalproex sodium extended-release	Depakote ER (250, 500 mg)	4–17 hr

LAMOTRIGINE

Lamotrigine (Lamictal) was developed as a result of screening folate antagonists as anticonvulsants. Lamotrigine proved effective in several animal models of epilepsy, was developed as an antiepileptic drug, and was marketed for the adjunctive treatment of partial seizures in the United States in 1995. Initial, postmarketing, open, clinical experience suggested efficacy in a variety of neurologic and psychiatric conditions, coupled with good tolerability (aside from the risk of rash). Later, double-blind, placebo-controlled studies revealed that lamotrigine was useful for some, but not all, of the neurologic and psychiatric conditions reported in open studies. Therefore, lamotrigine appeared effective as a maintenance treatment for bipolar disorder and was approved for the maintenance treatment of bipolar I disorder in 2003. Lamotrigine also appeared to have potential utility in acute bipolar depression. However, the magnitude of the effect was too modest to yield consistently superior performance compared with placebo, and hence lamotrigine did not receive approval for the treatment of acute bipolar depression.

Similarly, limited data suggested that lamotrigine had potential utility in rapid-cycling bipolar disorder. Lamotrigine did not appear to be as effective as the primary intervention in acute mania. Thus, lamotrigine has emerged as an agent that appears to "stabilize mood from below" in the sense that it may maximally impact the depressive component of bipolar disorders.

Pharmacologic Actions

Lamotrigine is wholly absorbed, has a bioavailability of 98 percent, and has a steady-state plasma half-life of 25 hours. However, the rate of metabolism of lamotrigine varies over a sixfold range, depending on which other drugs are administered concomitantly. Dosing is escalated slowly to twice-a-day

maintenance dosing. Food does not affect its absorption, and it is 55 percent protein-bound in the plasma; 94 percent of lamotrigine and its inactive metabolites are excreted in the urine. Among the better-delineated biochemical actions of lamotrigine is the blockade of voltage-sensitive sodium channels, which in turn modulates the release of glutamate and aspartate and has a slight effect on calcium channels. Lamotrigine modestly increases plasma serotonin concentrations, possibly through inhibition of serotonin reuptake, and is a weak inhibitor of serotonin 5-HT$_3$ receptors.

Therapeutic Indications

Bipolar Disorder. Lamotrigine is indicated in the treatment of bipolar disorder and may prolong the time between episodes of depression and mania. It is more effective in lengthening the intervals between depressive episodes than manic episodes. It is also useful as a treatment for rapid-cycling bipolar disorder.

Other Indications. There have been reports of therapeutic benefit in the treatment of borderline personality disorder and the treatment for various pain syndromes.

Precautions and Adverse Reactions

Lamotrigine is remarkably well tolerated. The absence of sedation, weight gain, and other metabolic effects are noteworthy. The most common adverse effects—dizziness, ataxia, somnolence, headache, diplopia, blurred vision, and nausea—are typically mild. Anecdotal reports of cognitive impairment and joint or back pain are standard.

The appearance of a rash, which is common and occasionally very severe, is a source of concern. About 8 percent of patients started on lamotrigine develop a benign maculopapular rash during the first 4 months of treatment, and the drug should be discontinued if a rash develops. Even though these rashes are benign, there is concern that, in some cases, they may represent early manifestations of Stevens–Johnson syndrome or toxic epidermal necrolysis. Nevertheless, even if lamotrigine is discontinued immediately upon the development of a rash or other signs of hypersensitivity reaction, such as fever and lymphadenopathy, this may not prevent subsequent

development of a life-threatening rash or permanent disfiguration.

Estimates of the rate of severe rash vary, depending on the source of the data. In some studies, the incidence of severe rashes was 0.08 percent in adult patients receiving lamotrigine as initial monotherapy and 0.13 percent in adult patients receiving lamotrigine as adjunctive therapy. German registry data, based on clinical practice, suggest that the risk of rash may be as low as 1 in 5,000 patients. The appearance of any rash necessitates immediate discontinuation of drug administration.

It is known that the likelihood of a rash increases if the recommended starting dose and speed of dose increase exceed what is recommended. Concomitant administration of valproic acid also increases risk and should be avoided if possible. If valproate is used, a more conservative dosing regimen is followed. Children and adolescents younger than age 16 years appear to be more susceptible to rash with lamotrigine. If patients miss more than 4 consecutive days of lamotrigine treatment, they need to restart therapy at the initial starting dose and titrate upward as if they had not already been on the medication.

Laboratory Testing

There is no proven correlation between lamotrigine blood concentrations and either antiseizure effects or efficacy in bipolar disorders. Laboratory tests are not useful in predicting the occurrence of adverse events.

Drug Interactions

Lamotrigine has significant, well-characterized drug interactions involving other anticonvulsants. The most potentially serious lamotrigine drug interaction involves concurrent use of valproic acid, which doubles serum lamotrigine concentrations. Lamotrigine decreases the plasma concentration of valproic acid by 25 percent. Sertraline (Zoloft) also increases plasma lamotrigine concentrations, but to a lesser extent than does valproic acid. Lamotrigine concentrations are decreased by 40 to 50 percent with concomitant administration of carbamazepine, phenytoin, or phenobarbital. Combinations of lamotrigine and other anticonvulsants have complex effects on the time of peak plasma concentration and the plasma half-life of lamotrigine.

Laboratory Interferences

Lamotrigine does not interfere with any laboratory tests.

Dosage and Administration

In the clinical trials leading to the approval of lamotrigine as a treatment for bipolar disorder, no consistent increase in efficacy was associated with doses above 200 mg/day. Most patients should take between 100 and 200 mg a day. In epilepsy, the drug is administered twice daily, but in bipolar disorder, the total dose can be taken once a day, either in the morning or night, depending on whether the patient finds the drug activating or sedating.

Lamotrigine is available as unscored 25-, 100-, 150-, and 200-mg tablets. The primary determinant of lamotrigine dosing is the minimization of the risk of rash. Lamotrigine should not be taken by anyone younger than 16 years of age. Because valproic acid markedly slows the elimination of lamotrigine, concomitant administration of these two drugs necessitates a much slower titration (Table 21-37). People with renal insufficiency should aim for a lower maintenance dosage. The appearance of any rash necessitates immediate discontinuation of lamotrigine administration. Lamotrigine should usually be discontinued gradually over 2 weeks unless a rash emerges, in which case it should be discontinued over 1 to 2 days.

Lamotrigine orally disintegrating tablets (Lamictal ODT) are available for patients who have difficulty swallowing. It is the only antiepileptic treatment that is available in an orally disintegrating formulation. It is available in 25, 50, 100, and 200 mg strengths and matches the dose of lamotrigine tablets. Chewable dispersible tablets of 2, 5, and 25 mg are also available.

CARBAMAZEPINE AND OXCARBAZEPINE

Carbamazepine (Tegretol) possesses some structural similarity to the TCA imipramine (Tofranil). It was approved for use in the United States for the treatment of trigeminal neuralgia in 1968 and temporal lobe epilepsy (complex partial seizures) in 1974. Interestingly, carbamazepine was first synthesized as a potential antidepressant, but because of its atypical profile in several animal models, it was initially developed for use in pain and seizure disorders. It is now recognized in most guidelines as a second-line mood

stabilizer useful in the treatment and prevention of both phases of bipolar affective disorder. A long-acting sustained release formulation (Equetro) was approved by the U.S. FDA for the treatment of acute mania in 2002.

Table 21-37
Lamotrigine Dosing (mg/day)

Treatment	Weeks 1–2	Weeks 3–4	Weeks 4–5
Lamotrigine monotherapy	25	50	100–200 (200 maximum)
Lamotrigine + carbamazepine	50	100	200–400 (400 maximum)
Lamotrigine + valproate	25 every other day	25	50–100 (100 maximum)

An analog of carbamazepine, oxcarbazepine (Trileptal), was marketed as an antiseizure medication in the United States in 2000. Previously it was used as a treatment for pediatric epilepsy in Europe since 1990. Because of its similarity to carbamazepine, many clinicians began to use it as a treatment for patients with bipolar disorder. Despite some reports that oxcarbazepine has mood-stabilizing properties, this has not been confirmed in large, placebo-controlled trials.

Carbamazepine

Pharmacologic Actions. The absorption of carbamazepine is slow and unpredictable. Food enhances absorption. Peak plasma concentrations are reached 2 to 8 hours after a single dose, and steady-state levels are reached after 2 to 4 days on a steady dosage. It is 70 to 80 percent protein-bound. The half-life of carbamazepine ranges from 18 to 54 hours, with an average of 26 hours. However, with chronic administration, the half-life of carbamazepine decreases to an average of 12 hours. This results from the induction of hepatic CYP450 enzymes by carbamazepine, specifically the autoinduction of carbamazepine metabolism. The induction of hepatic enzymes reaches its

maximum level after about 3 to 5 weeks of therapy.

The pharmacokinetics of carbamazepine are different for two long-acting preparations of carbamazepine, each of which uses slightly different technology. One formulation, Tegretol XR, requires food to ensure standard GI transit time. The other preparation, Carbatrol, relies on a combination of intermediate, extended-release, and very slow release beads, making it suitable for bedtime administration.

Carbamazepine is metabolized in the liver, and the 10,11-epoxide metabolite is active as an anticonvulsant. Its activity in the treatment of bipolar disorders is unknown. Long-term use of carbamazepine is associated with an increased ratio of the epoxide to the parent molecule.

The anticonvulsant effects of carbamazepine are thought to be mediated mainly by binding to voltage-dependent sodium channels in the inactive state and prolonging their inactivation. This action secondarily reduces voltage-dependent calcium channel activation and, thus, synaptic transmission. Additional effects include reduction of currents through N-methyl-D-aspartate (NMDA) glutamate-receptor channels, competitive antagonism of adenosine a_1-receptors, and potentiation of CNS catecholamine neurotransmission. Whether any or all of these mechanisms also result in mood stabilization is not known.

Therapeutic Indications

Bipolar Disorder

ACUTE MANIA. The acute antimanic effects of carbamazepine are typically evident within the first several days of treatment. About 50 to 70 percent of all persons respond within 2 to 3 weeks of initiation. Studies suggest that carbamazepine may be especially useful in persons who are not responsive to lithium (Eskalith), such as persons with dysphoric mania, rapid cycling, or an adverse family history of mood disorders. The antimanic effects of carbamazepine can be, and often are, augmented by concomitant administration of lithium, valproic acid (Depakene), thyroid hormones, DRAs, or SDAs. Some persons may respond to carbamazepine but not lithium or valproic acid and vice versa.

PROPHYLAXIS. Carbamazepine is effective in preventing relapses, particularly among patients with bipolar II disorder and schizoaffective disorder, and dysphoric mania.

ACUTE DEPRESSION. A subgroup of treatment-refractory patients with acute depression responds well to carbamazepine. Patients with more severe episodic and less chronic depression seem to be better responders to carbamazepine. Nevertheless, carbamazepine remains an alternative drug for depressed persons who have not responded to conventional treatments, including ECT.

OTHER DISORDERS. Carbamazepine helps to control symptoms associated with acute alcohol withdrawal, although benzodiazepines are more effective in this population. Carbamazepine has been suggested as a treatment for the recurrent paroxysmal component of PTSD. Uncontrolled studies suggest that carbamazepine is effective in controlling impulsive, aggressive behavior in nonpsychotic persons of all ages, including children and elderly persons. Carbamazepine is also effective in controlling nonacute agitation and aggressive behavior in patients with schizophrenia and schizoaffective disorder. Persons with prominent positive symptoms (e.g., hallucinations) may be likely to respond, as are persons who display impulsive aggressive outbursts.

Precautions and Adverse Reactions. Carbamazepine is relatively well tolerated. Mild GI (nausea, vomiting, gastric distress, constipation, diarrhea, and anorexia) and CNS (ataxia, drowsiness) side effects are the most common. The severity of these adverse effects is reduced if the dosage of carbamazepine is increased slowly and kept at the minimal effective plasma concentration. In contrast to lithium and valproate (other drugs used to manage bipolar disorder), carbamazepine does not appear to cause weight gain. Because of the phenomena of autoinduction, with consequent reductions in carbamazepine concentrations, side effect tolerability may improve over time. Most of the adverse effects of carbamazepine are correlated with plasma concentrations above 9 µg/mL. The rarest but most serious adverse effects of carbamazepine are blood dyscrasias, hepatitis, and severe skin reactions (Table 21-38).

BLOOD DYSCRASIAS. The drug's hematologic effects are not dose-related. Severe blood dyscrasias (aplastic anemia, agranulocytosis) occur in about 1 in 125,000 persons treated with carbamazepine. There does not appear to be a correlation between the degree of benign WBC suppression (leukopenia), which is seen in 1 to 2 percent of persons, and the emergence of life-threatening blood dyscrasias. Persons should be warned that the emergence of such symptoms as fever, sore throat, rash, petechiae, bruising, and easy bleeding can potentially herald a serious dyscrasia, and they should seek medical evaluation immediately. Routine hematologic monitoring in carbamazepine-treated persons is recommended at 3, 6, 9, and 12 months. If there is no significant evidence of bone marrow suppression by that time, many experts will reduce the interval of monitoring. However, even assiduous monitoring may fail to detect severe blood dyscrasias before they cause symptoms.

Table 21-38
Adverse Events Associated with Carbamazepine

Dosage-Related Adverse Effects	Idiosyncratic Adverse Effects
Double or blurred vision	Agranulocytosis
Vertigo	Stevens–Johnson syndrome
Gastrointestinal disturbances	Aplastic anemia
Task performance impairment	Hepatic failure
Hematologic effects	Rash Pancreatitis

HEPATITIS. Within the first few weeks of therapy, carbamazepine can cause both hepatitis associated with increases in liver enzymes, particularly transaminases, and cholestasis associated with elevated bilirubin and alkaline phosphatase. Mild transaminase elevations warrant observation only, but persistent elevations more than three times the upper limit of normal indicate the need to discontinue the drug. Hepatitis can recur if the drug is reintroduced to the person and can result in death.

DERMATOLOGIC EFFECTS. About 10 to 15 percent of those treated with carbamazepine develop a benign maculopapular rash within the first 3 weeks of treatment. Stopping the medication usually leads to resolution of the rash. Some patients may experience life-threatening dermatologic syndromes, including exfoliative dermatitis, erythema multiforme, Stevens–Johnson syndrome, and toxic epidermal necrolysis. The possible emergence of these serious dermatologic problems causes most clinicians to discontinue carbamazepine use in people who develop any rash. The risk of drug rash is about equal between valproic acid and carbamazepine in the first 2 months of use but is subsequently much higher for carbamazepine. If carbamazepine seems to be the only effective drug for a person who has a benign rash with carbamazepine treatment, a retrial of the drug can be undertaken. Many patients can be rechallenged without reemergence of the rash. Pretreatment with prednisone (Deltasone; 40 mg a day) may suppress the rash, although other symptoms of an allergic reaction (e.g., fever and pneumonitis) may develop even with steroid pretreatment.

RENAL EFFECTS. Carbamazepine is occasionally used to treat diabetes insipidus not associated with lithium use. This activity results from direct or indirect effects at the vasopressin receptor. It may also lead to the development of hyponatremia and water intoxication in some patients, mainly elderly persons, or when used in high doses.

OTHER ADVERSE EFFECTS. Carbamazepine decreases cardiac conduction (although less than the tricyclic drugs do) and can thus exacerbate preexisting cardiac disease. Carbamazepine should be used with caution in persons with glaucoma, prostatic hypertrophy, diabetes, or a history of alcohol abuse. Carbamazepine occasionally activates vasopressin receptor function, which results in a condition resembling the syndrome of secretion of inappropriate antidiuretic hormone, characterized by hyponatremia and, rarely, water intoxication. This effect is the opposite of the renal effects of lithium (i.e., nephrogenic diabetes insipidus). Augmentation of lithium with carbamazepine does not reverse the lithium effect, however. The emergence of confusion, severe weakness, or headache in a person taking carbamazepine should prompt the measurement of serum electrolytes.

Carbamazepine use rarely elicits an immune hypersensitivity response

consisting of fever, rash, eosinophilia, and possibly fatal myocarditis.

Cleft palate, fingernail hypoplasia, microcephaly, and spina bifida in infants may be associated with the maternal use of carbamazepine during pregnancy. Pregnant women should not use carbamazepine unless necessary. All women with childbearing potential should take 1 to 4 mg of folic acid daily, even if they are not trying to conceive. Carbamazepine is secreted in breast milk.
